FELLOW OF GONVILLE AND CAIUS COLLEGE, ETC. ETC.

PREFACE TO SIXTH EDITION

THE continued rapid advance of medical science, and the extending use and appreciation of this textbook, have made necessary the publication of this, the sixth edition, within four years of the appearance of its predecessor. It will readily be understood that the production, under wartime conditions, of a volume of this character and magnitude, has been a somewhat formidable task, which has been successfully accomplished only through the self-sacrificing labours of the contributors and the co-operation of the publishers.

The extent of the revision may be judged by the details set forth below, which are generally noted in the order of appearance of the respective articles throughout the work. It will be a source of satisfaction that, notwithstanding the very extensive revision, the size of the volume is practically the same.

The purpose and scope remain the same as when the work was originally conceived twenty years ago, namely, the presentation of a comprehensive survey of the practice of modern medicine in the form of a textbook, each subject being dealt with in an essentially practical manner, prominence being given to diagnosis, treatment, and prognosis, rather than to ætiology or pathology, although both these latter are dealt with in sufficient detail for ordinary reference.

In the new edition, the principal alterations in the general arrangement, classification, and nomenclature include: The sub-section on Diseases due to Filtrable Viruses is placed immediately after that on Bacterial Diseases. The articles on Acute Anterior Poliomyelitis, Lethargic Encephalitis, Herpes Zoster, and Rabies have been transferred from the sub-section due to Filtrable Viruses to form a sub-section of Diseases of the Nervous System, and the article on Multiple Myeloma from the section on Diseases of the Blood to that on Diseases of the Skeleton. Oroya Fever and Verruga Peruviana are included under the general term Bartonellosis. There is a new classification of Typhus and the Typhus-like Fevers; a re-arrangement regarding Toxic and Infective Diseases of the Liver; a re-classification of the Hæmorrhagic Diseases; a modification of the classification of Diseases of the Arteries; and a new arrangement regarding Meningeal Hæmorrhage and Chronic Subdural Hæmatoma. Changes in nomenclature are: Lymphopathia Venereum for Climatic Bubo; Upper Dysphagia with Anæmia (Paterson's (so-called Plummer-Vinson) Syndrome) for Dysphagia with Anæmia and Glossitis (Plummer-Vinson Syndrome); Methæmoglobinæmia and Sulphæ-

moglobinæmia for Enterogenous Cyanosis; and the Motor Neurone Disease for Progressive Muscular Atrophy.

New articles have been added on the following: The Common Cold, Leptospirosis, Epidemic Myalgia, Pink Disease, Injuries from X-rays, Injuries from Radio-active Substances, Manganese Poisoning, Poisoning by Coal-Tar Derivatives, Poisoning by Chlorinated Hydrocarbons, Adiposity, Diabetes Tenuifluus, Antihormones, Acute Suprarenal Deficiency, Virilism, Feminisation, Pseudo-Hermaphrodism, Sexual Precocity, the prescribing and administration of Hormone Preparations, Idiopathic Steatorrhœa, Tuberculosis of the Spleen, Chronic Tuberculous Lymphadenitis, Functional Bundle-Branch Block, the Heart in Hypothyroidism, Allergy, Adenoma of Bronchus, Congenital Cystic Disease of the Lung, Pneumonitis, Focal Osteitis Fibrosa, Dyschondroplasia, Sarcoidosis, Benign Aseptic Meningitis, Hypertensive Encephalopathy, Acute Disseminated Encephalomyelitis, Kernicterus, Rupture of the Intervertebral Disk, Acute Febrile Polyneuritis, Progressive Hypertrophic Polyneuritis of Dejerine and Sotta, and Neurofibromatosis.

Other new matter has reference to the use of the sulphonamide group of drugs in the treatment of acute infections, the use of a toxoid in the prophylaxis of Tetanus, skin tests and capillary fragility in Scarlet Fever, the classification of the Organisms causing Bacillary Dysentery, specific treatment in Oroya Fever, Verruga Peruviana, Malaria, American Dermal Leishmaniasis, Trypanosomiasis, Giardia Intestinalis, and in Thread Worms, the pathology and complications of Mumps, the symptoms and diagnosis of Amœbic Dysentery, the diagnosis and prophylaxis of Louse-Borne Typhus, Mercurial Poisoning, the use of the new insulins Protamine and Protamine Zinc Insulin, the treatment of Infantile Scurvy, the ætiology of Rickets, the Sub-Scurvy State, the Red Blood Cells, Clinical Electro-Cardiography, including the Fourth or Chest Lead, Chronic Miliary Tuberculosis, Epituberculosis and Hilar Flare, Oleothorax, Thoracoplasty and Extrapleural Pneumothorax in the treatment of Pulmonary Tuberculosis, the Superior Pulmonary Sulcus or Pancoast Tumour, the prognosis of Acute Nephritis, Familial Hæmorrhagic Nephritis, Sodium Diaphenyl hydantoinate (dilatin, epanutin) in the treatment of Epilepsy, Migraine, and the effects of the stress of war upon the mental health of soldiers and others.

The following portions have been entirely rewritten: The sections on Diseases of the Endocrine Glands and Diseases of the Joints and Inflammatory Diseases of the Fibrous Tissues. The articles on Lymphopathia Venereum, Spirochætosis Icterohæmorrhagica, Introduction to Rickettsia Diseases, Alcoholism, Lead Poisoning, tests for Hepatic Function, Acholuric Jaundice, Acute Infective Hepatitis, Aplastic Anæmia, Methæmoglobinæmia and Sulphænoglobinæmia, Melæna Neonatorum, the Aetiology of Agranulo-

cytosis, Niemann-Pick's Disease, Hand-Schüller-Christian's Disease, Irritable Heart of Soldiers, Primary Cardiac Strain, Auriculo-Ventricular Nodal Rhythm, Ventricular Fibrillation, Sino-Auricular Block, Chronic Adhesive Pericarditis, Tuberculosis of the Pericardium, the Surgical Treatment of Angina Pectoris, Hypertension, Raynaud's Disease, Hæmoglobinuria, the Pathology of Toxæmic Kidney, Osteitis Deformans, Leontiasis Ossea, Osteomalacia, Osteogenesis Imperfecta, Oxycephaly, Achondroplasia, Multiple Myeloma, the ætiology of Ménière's Disease, the treatment of Spasmodic Torticollis, the ætiology and pathology of Polyneuritis and Hæmatomyelia.

The following articles have been partly rewritten: Infection, Immunity, the treatment of Coliform Bacillus Infections, the methods of immunisation and of prophylaxis in Diphtheria, Yellow Fever, Syphilis, Yaws, Flea Typhus, Mite Typhus, Tick Typhus, the Clinical Aspects of Glandular Fever, Arsenical Poisoning, Beriberi, Pellagra, Tropical Macrocytic Anæmia, the pathology of Chronic Œsophageal Ulcer, the ætiology of Anorexia Nervosa, the surgical treatment of Ulcerative Colitis, Acute and Subacute Hepatic Necrosis, the Blood Volume, Symptomatic Hæmorrhagic States, the Treatment of Splenic Anæmia, Heart Failure, Auriculo-Ventricular Block, Pulsus Alternans, Chronic Valvular Disease, Acute Simple Myocarditis, Chronic Mycardial Disease, Hypertrophy and Dilatation of the Heart, Acute Pericarditis, Syphilitic Affections of the Aorta, the Heart, and the Pericardium, the treatment of Bell's Palsy, the signs of Local Lesions within the Skull and Brain, the pathology of Hydrocephalus and Craft Palsy.

An important innovation has been made in connection with the names of drugs. It was thought that a useful purpose would be served by the following: The English names in the *British Pharmacopœia* of 1932, or in one of its addenda, or in the *British Pharmaceutical Codex* are used. On the first occasion on which the official name is mentioned in the section on treatment of any particular disease, it is followed immediately by the name used in the *United States Pharmacopœia* when there is a material difference between the two. Next follow, almost always in brackets, the names of the more widely known of any proprietary preparations of corresponding composition, the British products usually being given priority, and, in the case of both the British and the foreign preparations, usually in alphabetical order. In the prescribing of drugs, following the recommendation in the *British Pharmacopœia*, grains and ounces for solids, and minims and fluid ounces for liquids, are used instead of the conventional symbols. It is a pleasure to express my indebtedness to Mr. H. Davis, Ph.D., A.I.C., Ph.C., for his valuable technical assistance in this connection.

There are 12 new illustrations (Figs. 51, 68, 82, 85, 86, 87, 89, 90, 92, 93, 94, and 95).

Drs. W. S. C. Copeman, Donald Hunter, Alan Moncrieff, and S. L.

Simpson are new contributors, and to them I desire to offer a warm welcome.

Since the appearance of the last edition Medical Science and Practice have suffered a great loss in the death of three of the contributors, namely, Otto Leyton, Edward Mapother, and William Henry Willcox, the last since this edition went to press. I desire to pay to their memory a profound tribute of regard and gratitude.

It may be considered not inappropriate if I offer a few remarks on this occasion. From the inception of this textbook, it met with a notable degree of appreciation from the class of readers for whom it was intended, and each successive edition has been received with an ever-growing measure of approval. Its circulation to-day is greater than ever in all English-speaking countries, and it is interesting to observe that its popularity abroad has increased in even greater measure than in the United Kingdom. These results suggest that the plan of the work as outlined in the Preface to the First Edition was fundamentally sound, and even, it may be said, anticipatory of the developments which have taken place in the teaching and practice of medicine. Apart from this original validity of conception, I attribute the success of the book to the high abilities and devoted efforts of my colleagues, the contributors, with whom from the beginning my relationship has been of the most intimate and happy character. No words of mine can adequately express my admiration and grateful appreciation of their help. All I can do is to tender them my cordial and abiding thanks. I desire to add that it has been an immense privilege to have been Editor of the first six editions of this Work.

I earnestly hope and venture to believe that this new edition will be, to an extent not less than its forerunners, of service alike to Teachers of Medicine, Consulting Physicians, and Senior Students, and that it may continue to be regarded as not unworthily representing British Medicine.

FREDERICK W. PRICE.

73 HARLEY STREET, LONDON, W.,

PREFACE TO FIRST EDITION

It is generally recognised that within recent years there has been a great advance in knowledge throughout the domain of Medicine. As an example of this might be cited the branch of cardiology. As the result of the introduction of the clinical polygraph and of the electro-cardiograph we are now able to analyse the cardiac action in a manner which was never possible before, and many of the problems in the study of diseases of the heart which have baffled clinicians for generations have been practically solved, while others are in process of solution. In the department of neurology the progress made has been scarcely less notable. It seemed to me, therefore, that now, more than ever, it has to be acknowledged that it is beyond the scope of any authority, however varied his range of knowledge, to do full justice to the ever-widening field of Medicine, and that a useful purpose might be served by the publication of a work of moderate compass and in one volume, in which the different branches of Medicine were dealt with by authors who have made a special study of them. It has also been thought advisable to include sections on Diseases of the Skin and Psychological Medicine. Tropical Diseases are also included.

In order to secure greater uniformity of method and style, I have generally adopted the principle of allotting a whole section to one author, or to two writing in collaboration, instead of enlisting the services of a large number of writers. I confidently anticipate that it will be recognised that I have been most fortunate in the selection of the various contributors to the volume, and I wish to offer to each of them my warmest thanks. I also desire to express my gratitude to Dr. A. P. Beddard, for the time he has very generously placed at my disposal, and for much valuable advice. It is a pleasant duty gratefully to acknowledge my indebtedness to Dr. Claude B. Ker for the use of blocks of figures taken from his *Manual of Fevers*, and to Dr. James Collier and Sir James Purves Stewart for a block of figure 96.

It is my earnest hope that the book may be considered a credit to the London School of Medicine.

FREDERICK W. PRICE.

CONTRIBUTORS

HAROLD S. BARWELL, M.B., F.R.C.S., Consulting Surgeon for Diseases of the Throat and Ear, St. George's Hospital.

G. E. BEAUMONT, M.A., D.M., F.R.C.P., D.P.H., Physician to the Middlesex Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest.

CHARLES R. BOX, M.D., B.S., B.Sc., F.R.C.P., F.R.C.S., Senior Physician to the Royal Masonic Hospital; Consulting Physician to St. Thomas's Hospital and to the London Fever Hospital.

SIR W. LANGDON BROWN, M.A., M.D., Hon. D.Sc.(Oxon.), F.R.C.P., Emeritus Professor of Physic in the University of Cambridge; Consulting Physician to St. Bartholomew's Hospital.

LIEUT.-COLONEL W. BYAM, Lecturer on Tropical Medicine, St. George's Hospital Medical School.

MAURICE CAMPBELL, O.B.E., D.M., F.R.C.P., Physician to Guy's Hospital and to the National Hospital for Diseases of the Heart.

W. S. C. COPEMAN, M.A., M.D., F.R.C.P., Physician to the British Red Cross Clinic for Rheumatism and Physician to the Department for the Treatment of Chronic Rheumatic Diseases, West London Hospital.

GEOFFREY EVANS, M.D., F.R.C.P., Physician to St. Bartholomew's Hospital.

N. HAMILTON FAIRLEY, O.B.E., M.D., D.Sc., F.R.C.P., D.T.M. & H., Physician and Director of Medical Research, Hospital for Tropical Diseases; Lecturer in Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine; Lecturer in Tropical Medicine, Westminster Hospital.

A. E. GOW, M.D., F.R.C.P., Physician to St. Bartholomew's Hospital.

GEORGE GRAHAM, M.D., F.R.C.P., Physician to St. Bartholomew's Hospital.

A. M. H. GRAY, C.B.E., M.D., F.R.C.P., F.R.C.S., Physician in charge of the Skin Department, University College Hospital; Consulting Physician for Skin Diseases, Hospital for Sick Children, Great Ormond Street.

BREVET-COLONEL L. W. HARRISON, D.S.O., M.B., CH.B., F.R.C.P.E., Consultant in Venereal Diseases, British Post-Graduate Medical School; Technical Adviser in Venereal Diseases, Ministry of Health.

LORD HORDER, K.C.V.O., M.D., B.Sc., Hon. D.C.L.(Dunelm), F.R.C.P., Consulting Physician to St. Bartholomew's Hospital.

DONALD HUNTER, M.D., F.R.C.P., Physician to the London Hospital.

SIR ARTHUR HURST, M.A., M.D., F.R.C.P., Consulting Physician to Guy's Hospital and Lecturer on Clinical Medicine, University of Oxford.

ROBERT HUTCHISON, M.D., LL.D., Hon.D.Sc.(Oxon.), F.R.C.P., Consulting Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond Street.

AUBREY LEWIS, M.D., F.R.C.P., Clinical Director, Maudsley Hospital; Consultant in Psychological Medicine, British Post-Graduate Medical School; and Lecturer and Examiner in Psychiatry, University of London.

G. CARMICHAEL LOW, M.A., M.D., F.R.C.P., Consulting Physician to the Hospital for Tropical Diseases and to the Seamen's Hospital, Royal Albert Docks, E.

J. W. McNEE, D.S.O., M.D., D.Sc., F.R.C.P., Regius Professor of the Practice of Medicine, University of Glasgow; Consulting Physician to University College Hospital, London.

EDWARD MAPOTHER, M.D., F.R.C.P., F.R.C.S., Professor of Psychiatry, University of London; Physician for Psychological Medicine to King's College Hospital; Medical Superintendent to the Maudsley Hospital.

JOHN MATTHEWS, B.A., M.B., B.Ch., Assistant in the Inoculation Department, St. Mary's Hospital; Hon. Bacteriologist, Star and Garter Home.

ALAN MONCRIEFF, M.D., F.R.C.P., Physician, Children's Department, Middlesex Hospital; Physician to Out-Patients, Hospital for Sick Children, Great Ormond Street.

R. H. A. PLIMMER, D.Sc., Professor of Chemistry in the University of London at St. Thomas's Hospital Medical School.

FREDERICK W. PRICE, M.D., C.M., F.R.C.P., F.R.S.(Edin.), Consulting Physician to the National Hospital for Diseases of the Heart and to the Royal Northern Hospital.

S. L. SIMPSON, M.A., M.D., F.R.C.P., Physician to the Willesden General Hospital and to the Princess Louise Kensington Hospital for Children; Consulting Physician to the Soho Hospital for Women.

E. G. SLESINGER, O.B.E., B.Sc., M.S., F.R.C.S., Surgeon to Guy's Hospital.

F. M. R. WALSHE, O.B.E., M.D., D.Sc., F.R.C.P., Physician in charge of the Neurological Department, University College Hospital; Physician to Out-Patients, The National Hospital for Nervous Diseases, Queen Square; Neurologist to the Hospital for Tropical Diseases.

SIR W. H. WILLCOX, K.C.I.E., C.B., C.M.G., M.D., B.Sc., F.R.C.P., Consulting Physician to St. Mary's Hospital; Senior Physician to the London Fever Hospital.

L. J. WITTS, M.D.(Vict.), F.R.C.P.(Lond.), Nuffield Professor of Clinical Medicine, University of Oxford.

R. A. YOUNG, C.B.E., M.D., B.Sc., F.R.C.P., Consulting Physician to the Middlesex Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest.

DISEASES OF THE INTESTINES 609
Introduction 609
I. The Functional Divisions of the Intestines 609
II. The Intestinal Movements. 610
III. Defæcation 611
Examination of the Intestines 611
Size, Shape and Position of the Colon. 611
Motor Functions 612
Examination of Fæces 614
Occult Blood 615
Proctoscopic and Sigmoidoscopic Examination 616
Functional Disorders of the Intestines 617
Constipation 617
Diarrhœa 622
Epidemic Diarrhœa in Children 629
Hill Diarrhœa 632
Cœliac Disease 633
Idiopathic Steatorrhœa 635
Sprue 638
Muco-Membranous Colic 642
Intestinal Carbohydrate Dyspepsia 644
Organic Diseases of the Intestines 646
Enteritis 646
Acute Enteritis 646
Chronic Enteritis 647
Regional Ileitis 647
Colitis 648
Acute Catarrhal Colitis 649
Chronic Catarrhal Colitis 649
Ulcerative Colitis 650
Tuberculous Enteritis and Colitis 655
Polypi of the Colon: Polyposis 656
Cancer of the Colon 657
Diverticulosis: Diverticulitis 660
Chronic Intussusception. 662
Anal Achalasia and Megacolon (Hirschsprung's Disease) . . . 663
Acute Intestinal Obstruction 670
Appendicitis 675
Acute Appendicitis 676
Recurrent Subacute Appendicitis, Chronic Appendicitis and Appendicular Dyspepsia 680
DISEASES OF THE LIVER 682
Tests for Hepatic Function 682
Jaundice 683
Simple Jaundice in Infants (Icterus Neonatorum) 688
Familial Icterus Gravis Neonatorum 688
Acholuric Jaundice 689
Congestion of the Liver 691
Glycogen Disease (Von Gierke's Disease) 692
Infections of the Liver 693
Catarrhal Jaundice 693

Acute and Subacute Hepatic Necrosis 695
Acute Hepatic Necrosis (Acute Yellow Atrophy of the Liver; Icterus Gravis) 696
Subacute Hepatic Necrosis 697
Treatment of Acute and Subacute Hepatic Necrosis 697
Acute Infective Hepatitis 698
Cirrhosis of the Liver 698
Alcoholic Hepatitis 699
A. Pre-Cirrhotic Alcoholic Hepatitis 699
B. Cirrhosis of the Liver 700
Hæmochromatosis 707
Amœbic Hepatitis and Hepatic Abscess 708
Acute and Subacute Amœbic Hepatitis and Hepatic Abscess . . 709
Chronic Amœbic Hepatitis 711
Syphilis of the Liver 712
Congenital Syphilis (Pericellular Cirrhosis) 712
Acquired Syphilis 713
Hydatid of the Liver 715
Carcinoma of the Liver 717

DISEASES OF THE PORTAL VEIN 721
Non-suppurative Pylephlebitis and Portal Thrombosis 721
Suppurative Pylephlebitis 721

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS 722
Cholecystitis 722
Acute Cholecystitis; Empyema of the Gall-bladder . . . 724
Chronic Cholecystitis 724
Gall-stones 728
Biliary Colic without Gall-stones 732
Carcinoma of the Gall-bladder 733
Congenital Obliteration of the Bile-ducts 734
Carcinoma of the Bile-ducts 735

DISEASES OF THE PANCREAS 736
The Investigation of Diseases of the Pancreas 736
Acute Necrosis of the Pancreas 737
Subacute Necrosis of the Pancreas 739
Chronic Pancreatitis 740
Syphilis of the Pancreas 742
Pancreatic Calculi 742
Pancreatic Cysts 743
Carcinoma of the Pancreas 744

VISCEROPTOSIS 746

GASTRO-INTESTINAL ALLERGY 751

DISEASES OF THE PERITONEUM 752
Acute Peritonitis 752
Chronic Peritonitis 759
Tuberculous Peritonitis 759
Cancer of the Peritoneum; Malignant Peritonitis 763
Ascites 764

A TEXTBOOK OF THE PRACTICE OF MEDICINE

SECTION I

INFECTION

Effects of Bacterial Activity

When a bacterial invasion of the body tissues occurs the result is disease; the process is spoken of as an infection, and the bacterium is said to be pathogenic. The terms "pathogenic" and "non-pathogenic" are by no means rigid. No organism is pathogenic to all animals, and even organisms generally pathogenic to a given species may be introduced into an individual of that species, even in considerable quantity, without producing disease. On the other hand, organisms usually saprophytic, when introduced in sufficient quantity into an animal of a species usually immune, may cause disease.

Organisms pathogenic for one species of animal are frequently non-pathogenic for other species, and not a few organisms are pathogenic for man alone, except under certain exceptional experimental conditions.

Certain organisms which habitually exist under normal conditions as saprophytes in one part of an animal's body, may at the same time be the cause of an active infection in another part. For example, a member of the coliform group of intestinal bacilli, usually a harmless saprophyte in the intestine, may be simultaneously the cause of an active infection in the bladder. Bacteria which usually function as harmless saprophytes, but under certain conditions become pathogenic, are termed "commensals." Again, micro-organisms that are potentially infective may and do exist under saprophytic conditions; that is to say, apart from the animal body, and under different conditions as regards temperature, etc. Saprophytic bacteria that are incapable of invading living animal tissues may yet invade the animal body when any part thereof is so injured as to be dead, or is in process of dying. Certain varieties of bacteria, usually infective, may become saprophytic. The hosts are then termed "carriers." The best known examples thereof are the typhoid bacillus, the diphtheria bacillus and the meningococcus. The two former examples generally, if not always, occur after an infection, whereas the meningococcus is more often found existing in a saprophytic than in a pathogenic state. In these cases the bacteria do not exert any apparent harmful effect, but they are, of course, of great potential danger to the surrounding community.

A similar condition exists in connection with the paratyphoid bacilli and those of the food-poisoning group generally. This condition differs to some slight extent from that of the carriers noted above, in that there is some evidence, continuous or recurrent, of constitutional disturbance, though in the periods between recurrence, which may be prolonged, the condition closely resembles that of a carrier.

Infective bacteria are generally aerobic, or facultatively aerobic. True anaerobes have very little power of spreading through uninjured animal tissues unless they are accompanied by aerobes, though they may cause localised infections in tissues in which the oxygen supply is limited. Hence the bacteria usually associated with infections are aerobic organisms that flourish at body temperature.

A microbe may belong to a highly infective variety and yet its infectivity vary greatly. This property is known as *virulence*, and depends on various factors.

The *path of infection* also has a determining influence. Thus, staphylococci injected subcutaneously in a rabbit produce a local abscess, while if the injection be intravenous, pyæmic abscesses may lead to death. Typhoid bacilli must be swallowed to be infective, while it has been demonstrated that plague may be caused by rubbing *B. pestis* into the skin.

Subject of infection.—Healthy individuals differ greatly in their reaction to infective microbes, because of individual, racial or environmental characteristics, or because of age.

A *local susceptibility* may be brought about by trauma or interference with the circulation, conditions which may permit even anaerobic organisms to flourish.

An existing disease may modify the reaction of the host to an infection. Thus the subjects of diabetes are prone to staphylococcal and tuberculous infections.

Bacteria that are capable of spreading in the tissues usually have the power of causing *septicæmia*, that is, of flourishing in the blood stream, and, as a sequel, of producing *pyæmic* processes. Other bacteria causing acute infections appear in the blood stream during the earlier stages of the infection, but in the later stages tend to disappear therefrom, the *bacteriæmia* being incidental to, but not coextensive with, the infection. Streptococci and staphylococci are common examples of the former process, and the typhoid bacillus of the latter.

Results of Bacterial Infection

If the individual be in a healthy state, even a large quantity of virulent micro-organisms can gain admission to the body, and, owing to the local defences, may be destroyed before damage occurs; such a repelled invasion may cause no symptoms. When the local defences prove inadequate to ensure the complete destruction of the invading bacteria, the result is a local, or general, infection, or both.

A local infection may result in cellulitis or abscess formation, associated with more or less absorption of poisonous products; such a local infection may become generalised, leading to septicæmia or pyæmia. But whether the infection be local or general, or both, a greater or less degree of general

poisoning may occur, by reason of soluble poisons elaborated by the bacteria. These poisons are termed " toxins." *Toxins* are of two varieties—exotoxins and endotoxins.

Exotoxins are soluble poisons elaborated by certain classes of bacteria—notably diphtheria and tetanus. These exotoxins are destroyed by comparatively low temperatures; for instance, diphtheria toxin is destroyed by a temperature of 65° C. When an exotoxin is introduced into an animal's body, the specific effects thereof appear after an incubation period. *Endotoxins* can only be recovered by autolysis or trituration of the micro-organisms whch produce them. This means that those bacteria which only elaborate endotoxins can only poison an animal by proliferating within the tissues of that animal, while the poisoning produced by exotoxin may occur without invasion of the body by the organism concerned. Endotoxins will withstand a temperature of 100° C.

The difference between exotoxin and endotoxin is a fundamental one in specific therapy, as in a toxæmia from exotoxin a suitable antitoxin in appropriate amount constitutes an adequate defence, while in the case of toxæmia from an endotoxin the bacterium itself has to be proceeded against. The mode of action of toxins is very variable and depends upon the variety of bacterium. The toxins of diphtheria and tetanus tend to produce profound poisoning effects on the nerve tissues. Those consequent upon other infections produce other effects, prominently fever and degenerative changes in the tissues.

IMMUNITY

Definition.—Immunity is that function of the animal organism by virtue of which the effects of bacterial activity are resisted. Immunity is either natural or acquired.

Natural Immunity

Factors determining immunity are not well understood; but environment, habits, age and race partly account for them. The natives of countries where certain diseases are endemic may be far more resistant to those diseases than inhabitants of countries where the diseases are not endemic, as shown by the resistance of the negro to yellow fever. Conversely, diseases that have existed in mild forms for years endemically among one race may cause a veritable plague when introduced to a fresh race. Thus tuberculosis ravaged the North American Indians, and syphilis when introduced to Europe from America, where it was probably endemic, followed the course of an epidemic of a highly contagious disease.

There is also individual immunity, as shown by the fact that in any epidemic some individuals entirely escape infection, while in those infected all degrees of resistance are noted. In contradistinction to individual natural immunity, which condition does not lend itself to analysis, there is the condition of individual susceptibility—a condition to which considerable study has been devoted, chiefly in the direction of non-bacterial toxæmias, such as hay fever and the various toxic idiopathies.

Acquired Immunity

(i) *As the result of recovery from infection*

When an individual has recovered from certain infections such as typhoid fever, scarlet fever, measles and the other exanthemata, he commonly experiences immunity from those diseases in future. The duration of this form of acquired immunity varies greatly with different infections: that following influenza and pneumonia may be quite short. This acquired immunity was recognised centuries ago, and history shows that attempts at protection were made by inoculating infective material; it was on account of this knowledge that Pasteur began the study of protective inoculation which forms the basis of our knowledge of immunity.

(ii) *Artificial Immunity; Active and Passive*

Pasteur, in 1880, showed that injections of attenuated cultures of the organism of chicken cholera would protect the inoculated fowl against lethal doses of the virulent bacilli. From this observation resulted artificial immunity, and because the protection is elaborated solely by the action of the tissues of the infected animal, the term Active Immunisation was introduced by Ehrlich.

Von Behring, in 1890, discovered that the serum of actively immunised animals when transferred to other animals conferred immunity on the latter, and this process is termed Passive Immunity. It differs broadly from active immunity in that the protection afforded is comparatively transient, depending as it does on the actual amount of immune substance introduced.

Antitoxins

As already stated, toxins are of two kinds—exotoxins and endotoxins. The former exert their effects independently of the bacteria that produce them, while the latter only become effective when their parent microbes become dissolved. The injection of suitable doses of exotoxin calls forth the response of antitoxin; whereas the injection of suitable doses of endotoxin, *i.e.* vaccine, calls forth the response of bacterial antibodies. It is now known that other bacteria than those of diphtheria, tetanus and Shiga's dysentery produce appreciable quantities of antitoxin, namely *Streptococcus scarlatinæ*, *B. botulinus* and *Staphylococcus pyogenes*.

Since von Behring and Kitasato demonstrated the antitoxic properties of the blood of animals immunised against diphtheria toxin in 1890, an immense amount of work has been published, and improvements in the preparation of antitoxin have constantly accrued.

A unit of toxin is that quantity sufficient to kill a 250 g. guinea-pig in 4 days. The original Ehrlich unit of antitoxin was that amount that would save the life of a 250 g. guinea-pig injected with 100 units of toxin, but owing to variations in the strength and keeping qualities of different batches of toxin, the present unit of antitoxin is the amount of antitoxin

in a known weight of dried antitoxic serum preserved in England, the United States of America and Germany.

The preparation of diphtheria and tetanus antitoxins is comparatively simple, as is also the preparation of scarlatina antitoxin, but the preparation of powerful staphylococcal antitoxin is proving difficult.

Other anti-sera of therapeutic value are those prepared against infection by meningococcus, pneumococcus, streptococcus, anthrax, clostridium welchii, *B. dysenteriæ* and leptospira icterohæmorrhagiæ. The use of several of these sera has been considerably restricted since the recent expansion of chemotherapy.

The Properties of Immune Sera

Von Behring's discovery that the sera of immune animals could passively confer immunity shows that such immune sera contain substances either different from those, or in excess of those, present in normal sera; and, in 1894, Pfeiffer showed that if cholera spirilla were injected into the peritoneal cavity of a highly immunised guinea-pig, the bacilli lost motility, became granular and swollen, and finally disappeared. This phenomenon became known as Pfeiffer's phenomenon, or Bacteriolysis. It was then shown by Metchnikoff and Bordet that a similar result occurred *in vitro* in a mixture of heated immune serum and cholera vibrios if, and only if, normal serum be added. As a result of these and subsequent researches it was recognised that two substances are present in immune sera, one of which is peculiar to immune and the other common to immune and normal sera. The former, originally called " substance sensibilitrice " (Bordet), is now generally known as *amboceptor* (Ehrlich); while the latter, formerly called alexin by French writers, is now usually known as *complement* (Ehrlich).

It will also be recognised that the specific change that has occurred in an immune serum is the presence of amboceptor, which can only act in the presence of complement. Amboceptor is specific in that it only acts in connection with the bacterium or inoculating substance which calls it forth (antigen), while complement acts independently and in connection with amboceptor of any kind.

Bacteriolysis also occurs in connection with typhoid immune sera, but many other varieties of bacteria are not subject to it; it can, however, be demonstrated that those organisms, immunity against which is unaccompanied by bacteriolysis, are susceptible to other properties of immune sera. In connection, however, with bacteriolysis must be mentioned hæmolysis. Bordet, in 1898, showed that if an animal be immunised with the corpuscles of another species the serum of the immune animal acquires the property of destroying the red corpuscles of that species. This phenomenon of hæmolysis has become of great importance, as it forms the indicating phenomenon in the complement deviation test of Bordet and Gengou, and of its modification the Wassermann reaction. Similarly many other cytotoxic sera can be elaborated by injecting emulsions of appropriate cells.

Agglutinins.—The agglutination of bacteria in the presence of the serum of an immune animal was first observed by Charrin and Roger in 1889, and as a specific reaction was described by Gruber and Durham in 1896, when

Grünbaum and Widal simultaneously recognised the great importance of this reaction from a diagnostic point of view in the case of typhoid fever.

If bacterial substance be introduced into the tissues of an animal, either by infection or injection, agglutinin is formed, and will cause agglutination of the agglutinable substance in an emulsion of the homologous bacteria. The bacterial substance is an antigen, and inasmuch as it appears to be identical with the agglutinable substance, the latter is also frequently alluded to as antigen.

Agglutination occurs in two stages. In the first, sensitisation of the bacteria by a specific substance in the immune serum, agglutinin, occurs: and in the second, the bacteria adhere together, in clumps, and gradually settle by gravity. Such clumping only occurs in the presence of low dilutions of salts, acting as electrolytes.

Agglutination does not affect the vitality of bacteria, and it occurs with living or dead bacteria. Agglutinins are relatively thermostable, though an agglutinating serum which has been heated to between 62° to 70° C., or which has been kept for a long time, may show "zones" of agglutination, *i.e.* that with low and high dilutions of serum agglutination occurs, but with intermediate dilutions there may be no agglutination.

Among motile bacteria two types of antigen occur, the flagellar termed H, and the somatic termed O, and the agglutinins resulting from each have different characteristics. H agglutination results in large loose flakes, and H antigen is usually labile at temperatures of from 80° to 100° C., while the O agglutination results in small compact flakes, and the antigen resists a temperature of 100°. The H agglutinins tend to persist in an animal serum for a long time, and also tend to reappear in a patient's blood during a non-specific fever, so care must be exercised in reading a moderately high agglutination as diagnostic of the existence of infections of the enterica group. These considerations do not hold in connection with diseases such as undulant fever, or dysentery, as the O agglutinins do not tend to persist, or to be regenerated by non-specific fevers. In general, H agglutinations are rapid and may be read after 2 hours. O agglutinations are less rapid, and are seen at their best after 12 hours. The H antigens are generally more specific than the O antigens. For example, the O antigens of *B. typhosus* and *enteritidis* are very similar, if not identical, but their H antigens are quite specific. In the case of the Proteus group, however, the O antigens are far more specific than the H antigens within the limits of the group.

Felix and Pitt have shown that in the case of the typhoid bacillus, and possibly also in Salmonella infections, there is a marked difference in smooth strains, in that some are far more virulent than others. They have shown that strains recently isolated tend to be virulent because they possess a "Vi" antigen in addition to the H and O antigens of the smooth type of typhoid bacillus. The virulence of any smooth type being examined is tested by the intraperitoneal injection of mice, the test dose being 100×10^6 bacilli.

Vi antigen is heat labile, and agglutinative tests to demonstrate its presence must be carefully carried out with living suspensions at body temperature.

In practice the patient's serum, in a series of graded dilutions, is mixed with suspensions of fresh or preserved bacteria, and the mixtures incubated at 55° C. The highest dilution of serum containing specific agglutinins varies within wide limits according to the nature and state of the infection.

With regard to the enterica group, the following are usually considered as diagnostic:

B. typhosus . . .	1 in 64 or higher.
B. paratyphosus A . .	1 in 32 or higher.
B. paratyphosus B . .	1 in 128 or higher.

For classifying bacteria recovered from patients, specific immune sera are employed, the titre of which will be known, and the limits of agglutination denoting pathogenicity indicated.

Precipitins.—To a filtrate of cholera vibrios Kraus added anti-cholera serum, and incubated the mixture at 37°. After some time flocculi appeared. The same phenomenon occurred with typhoid filtrates and anti-typhoid serum, and in the course of time precipitating sera were prepared against a great variety of antigens, animal, bacterial and vegetable. It was found by Danysz, subsequently elaborated by Dean, that optimal proportions of antibody and antigen played an important part in the successful performance of the test, and it appears that a relative excess of either hinders the reaction. The strength of sodium chloride solution used has some effect also on the reaction, and Dean has shown that 0·2 per cent. is the most favourable. Originally it was thought that precipitin so acted on antigen—precipitinogen—as to precipitate the protein thereof, but it has been shown by many workers that the bulk of the precipitate is derived from the proteins of the antiserum. This is in obvious contrast to the agglutination reaction, in which the agglutinated bacteria are clearly derived from the agglutinogen.

The reaction is turned to account in Forensic Medicine, in the recognition of human blood in blood stains, in the recognition of the meat of different species of animals, and even in the detection of cereal adulterants. Methods of estimation of the strengths of toxins and antitoxins are also based on the precipitin reaction.

Anaphylaxis.—When a foreign protein is introduced into an animal, hyper-susceptibility may be produced, which hyper-susceptibility can be demonstrated by injecting after the lapse of ten days a further—in itself non-lethal—dose of the protein, when there occurs a condition varying from slight signs of illness ranging through various stages of respiratory distress up to sudden death. A second injection of antitoxin after a sufficient interval may produce anaphylaxis. In consequence of this the question of desensitisation becomes of great importance. If at some period more than 10 days after an injection of antitoxin it is desired to give a further dose the presence of the anaphylactic state should be negatived. This is done by a skin reaction. A small quantity, say 0·05 c.c., of normal horse serum (or antitoxin) is injected intradermally, or rubbed into a scarified surface. There occurs, if anaphylaxis—or a toxic idiopathy to horse substance—exists, an urticarial patch sometimes progressing to a vesicular eruption with a surrounding area of erythema. This usually occurs within half an hour, but is occasionally delayed. If anaphylaxis be demonstrated, the patient should be desensitised. If time be not of paramount importance, 0·025 c.c. of antitoxin is administered subcutaneously, and the amount is doubled every half hour. After 1 c.c. has been given, subsequent doses are given intravenously until 25 c.c. in all have been administered. When serum is being given to a patient whose idiosyncrasy is unknown, 1 c.c. of 1 in 1000 adrenaline

in a syringe should be at hand lest symptoms of anaphylaxis should appear.

Serum sickness.—The use of horse serum, whether normal or immunised, and especially when given by the subcutaneous route, often leads to certain symptoms of a non-specific character on or about the eighth day after the first dose has been administered. These symptoms consist of an urticarial rash, with pruritus which may be very troublesome, mild pyrexia, pain in and swelling of the joints and some malaise. The urticaria may be concentrated about the site of injection of the serum, or it may be generalised. There may be local or general œdema, but the latter is uncommon; so, too, are albuminuria and swelling of the lymph glands. In some cases the local urticaria appears much earlier than the eighth day; it may appear within a few hours of the initial puncture, the more general symptoms showing themselves towards the end of the week. "Serum sickness" is rarely serious. Treatment is by anti-pruritic lotions, such as saturated bicarbonate of soda solution, or dilute carbolic acid (1 : 100) or lotio calaminæ co, and by aspirin internally. It may be added that if the joint symptoms precede the rash—a rare event—some difficulty may arise in diagnosis.

THE FILTRABLE VIRUSES

A number of human diseases, examples of which are small-pox, rabies, yellow fever, chicken-pox, measles and epidemic poliomyelitis, are now known to be caused by ultra-microscopic viruses, and, arguing from analogy, encephalitis lethargica is thought to belong to the group, though proof is still lacking.

As a rule, these viruses measure less than 250 $\mu\mu$, and some of them measure much less. Particles less than 250 $\mu\mu$ cannot be resolved by ordinary microscopes, though Barnard, by the use of a short-wave ultra-violet light and lens systems of quartz has resolved objects as minute as 75 $\mu\mu$. Great diversity of size occurs amongst the viruses. For instance, that of foot-and-mouth disease of cattle measures about 12 $\mu\mu$, while that of pleuro-pneumonia of cattle, which occurs in two forms, measures from 150 $\mu\mu$ to 250 $\mu\mu$. With few exceptions, however, the viruses are ultra-microscopic, and will pass through filters that fail to pass the ordinary bacteria. The properties of the porcelain filters used vary considerably, and other factors besides the actual diameter of the pores have to be taken into account. Thus, the substance of the filter may adsorb the virus, even though the pores of the filter may be sufficiently large for its passage. The flexibility of the virus, and the pressure of filtration may also introduce variable factors. It follows, therefore, that the failure of a virus to pass through a filter does not necessarily mean that its particles are too large.

Though differing much in size and effects, most of the viruses have characteristics in common. Many of the diseases caused by filtrable viruses in man and animals are highly infectious, very minute doses of virus causing infection—an infection that spreads with great rapidity. Many of the virus diseases produce special intracellular bodies, termed inclusion bodies. These may be restricted to one particular tissue, or may be found in various tissues. They may occur in the cytoplasm or nuclei of cells, or in both, and vary

greatly in size. In some diseases the diagnosis can be made histologically by the recognition of these bodies, *e.g.* the Negri bodies in rabies. The fact that the inclusion bodies have been seen to develop *in vitro* in tissue-cultures suggests that the filtrable viruses are intracellular parasites, in which respect they differ from the majority of bacteria.

Some of the virus diseases, such as yellow fever, dengue and papataci fever, are insect-borne.

With the exception of pleuro-pneumonia of cattle, no virus has been cultivated *in vitro* in the absence of growing cells, though many can be propagated in tissue cultures, and on account of this exception, many, if not the majority of workers, hold the opinion that pleuro-pneumonia is not a virus disease. Generally speaking, therefore, viruses can only be propagated by animal passage.

Most of the viruses produce an active immunity which is very lasting, and in some of the diseases immune serum confers passive immunity. In measles the injection of immune serum will produce such a degree of passive immunity as to prevent an attack of measles in a contact, but such immunity is not lasting. If given about 6 days after contact, a modified attack of measles of very attenuated type will occur, subsequent to which permanent immunity ensues. Valuable clinical results have been claimed by many workers from the use of immune serum in the pre-paralytic stage of poliomyelitis, but the exact value of the method is difficult to assess. With few exceptions all agree that immune serum has no effect when once paralysis has supervened. Recent work published by the Rockefeller Institute shows that fully inactivated yellow fever virus will not confer immunity. Inactivated distemper virus will, however, immunise, and is indeed used as a preliminary measure in the prophylaxis of distemper, and inactivated virus also confers immunity in cattle plague, fowl plague, rabies, influenza (in mice), herpes and some other animal diseases.

Most of the filtrable viruses are resistant to glycerine, especially at low temperature, and remain unaltered for long periods in 50 per cent. thereof at 4° C., whereas the lethal effect of glycerine on bacteria generally is well known.

Complement fixation reactions between virus and antibody have been shown in many virus infections, and flocculation has been shown in the case of variola virus. Ledingham has shown that homogeneous suspensions of the elementary corpuscles from vaccinia and fowl-pox are agglutinated by the sera of convalescent animals, while normal serum has not this effect.

The following list comprises some of the human virus diseases under three headings:

1. *Certain*

Small-pox.
Chicken-pox.
Mumps.
Yellow Fever.
Dengue Fever.
Phlebotomus Fever.
Rift Valley Fever.
Lymphopathia Venereum.
Herpes Febrilis.
Herpes Zoster.
Infectious Warts.
Acute Anterior Poliomyelitis.
Psittacosis.
Rabies.
Encephalitis (St. Louis Type).
Influenza.

2. *Almost Certain*

Measles.
Encephalitis Lethargica.
Molluscum Contagiosum.
Rubella.

3. *Possible*

Common Cold.

BACTERIOPHAGE

In cultures of bacteria certain areas of transparence, increasing at the expense of the growth, have been recognised for years by bacteriologists, but had not attracted much attention, being dismissed as due to autolysis, until, in 1915, Twort found that the process could be transferred to fresh cultures indefinitely. He also showed that the lytic principle could be transferred in filtrates free of bacteria. He discussed the possibility of an ultra-microscopic virus being responsible.

D'Herelle, in 1917, carried out an important research on the phenomenon, and maintained that the lysis was due to an ultra-microscopic virus, to which he gave the name "Bacteriophage."

Much controversy has arisen as to the true nature of bacteriophage, two main opinions emerging—(1) that it is a living ultra-microscopic virus, and (2) that it is a ferment supplied by the bacteria themselves. All authorities appear to agree that the actual lytic agent is an enzyme, but disagree as to the origin of the enzyme.

Bacteriophage is very resistant to many influences deleterious to bacteria. Many specimens require 75° C. for half an hour to ensure destruction. Fæces sealed up in tubes for more than a year may still show bacteriophage. D'Herelle found it withstood 1 in 200 perchloride of mercury and 1 in 100 carbolic for 3 days.

Usually a bacteriophage to one organism has no effect upon a different variety, though a certain amount of overlapping with allied strains occurs.

Bacteriophage can act as an antigen, and when injected into an animal produces an antiserum which inhibits the lytic action.

JOHN MATTHEWS.
HORDER.
A. E. GOW.

SECTION II

INFECTIOUS DISEASES

A. BACTERIAL DISEASES

The main results of the invasion and infection of the body by micro-organisms are discussed in the section upon infection and immunity. It is important to distinguish clearly between "invasion," "infection" and "intoxication," and the reader is referred to the section mentioned for the consideration of these several processes.

TOXÆMIA

This term is applied to the condition of a patient who is absorbing into the tissues and circulation toxins elaborated at some local site of microbic infection. The diseases caused by the specific microbes of diphtheria and tetanus are examples of toxæmia, the sites of infection being in the former disease the fauces or larynx, and in the latter disease the damaged tissue about a wound or abrasion. The symptoms of toxæmia are variable, and depend upon the special affinity that the toxins concerned have for certain tissues or organs. There are, therefore, general symptoms common to many microbic infections: fever, rigors, malaise, vomiting, pains in the back and limbs, headache, sweating, etc.; and special symptoms, such as are manifested by an affinity of the toxin for nerve structures (paralyses, spasms, delirium, etc.), or for the heart (arryhthmia, tachycardia, cardiac asthenia, etc.), and others.

One form of toxæmia of great importance is that known as *Focal Sepsis*. In this condition there may be few or no symptoms referable to the primary local site of infection, yet the resulting toxæmia may manifest itself as fibrositis, arthritis, anæmia, rarefaction of bone, loss of weight, pyrexia, or a combination of these. In focal sepsis, pyrexia is not a marked feature except in some cases of coliform infection of the urinary tract and in a minority of dental apical infections. The likely sites for focal sepsis are the nasal sinuses, the teeth, the tonsils, the bronchi, the gall-bladder, the appendix, the intestinal tract and the genito-urinary tract in both sexes. Chronic infection may lurk in certain of these situations even in the absence of gross macroscopic lesions. The tonsils, for example, though not enlarged, may contain pus or inspissated secretion in their crypts: a scarred and ragged tonsil, or one which has venules on its surface is always suspect, especially when the lymph node behind the angle of the jaw is palpable. The search for focal sepsis must be thorough and systematic, and may necessitate certain

instrumental investigations, *e.g.* X-ray examination of the cranial sinuses, of the apices of the teeth and the periodontal membranes; a cholecystogram; a catheter for a specimen of urine; a speculum for a view of the cervix uteri. Bacteriological examination of a post-nasal swab, or of the apex of a tooth at the time of extraction, or of a catheter specimen of urine, of any uterine discharge, of material obtained after prostatic massage, or of the stools, etc., may be required. The correct interpretation of the findings from such investigations is often difficult.

SEPTICÆMIA

Septicæmia is a condition in which the infecting microbe transgresses the tissue barrier at the site of local infection and invades the blood stream, multiplying therein, and thus continuing the infection in a general manner. The mere existence of the microbe in the blood stream is not to be considered as necessarily constituting a true septicæmia. Thus we know that during the first few days of an attack of typhoid fever, of pneumonia, and of certain other diseases, the specific microbe can very often be isolated from the circulation by blood culture. The more thoroughly the investigation of microbic infections by blood culture is undertaken, the more patent it becomes that at some stage or other the infecting organism exists in the circulation. *Bacteriæmia* is a convenient term by which to express the (temporary) existence of micro-organisms in the blood stream in other states than true septicæmia.

There are two main conditions of septicæmia in so far as this is related to the local infection. (1) The local infection may be obvious, the septicæmia clearly resulting from this; or (2) no local infection may be discoverable, or the local infection may be, at best, merely surmised. Even at a careful post-mortem examination the source of local infection may not be manifest in some of the cases illustrating this type of septicæmia.

The *microbes chiefly concerned in septicæmia* are *Staphylococcus aureus*, *Streptococcus pyogenes* (vel *hæmolyticus*) and the pneumococcus. Much less commonly the gonococcus, Pfeiffer's bacillus, the meningococcus, and *B. pyocyaneus* perform this rôle.

The *local infections tending to lead to septicæmia* are chiefly concerned with the throat (streptococcus), the uterus ("puerperal fevers"), the subcutaneous tissues of the hand and foot (infections during operations and post-mortem examinations, septic wounds, etc.), and the site of surgical operations (post-operative septicæmia).

Symptoms.—The symptoms in septicæmia vary much; there is also great variation in the intensity and course of the disease. Some of the worst cases from the point of view of prognosis are those in which physical signs are conspicuous by their absence, whether as regards the site of the local infection or as regards the development of secondary lesions (thromboses, visceral inflammations, etc.). Thus, in a case of puerperal septicæmia, if a careful examination of the pelvic organs reveals no defect in the uterus or its adnexa, and if no signs of local concentration of the infecting agent be found elsewhere, the case is likely to be one of great anxiety.

The symptoms include pyrexia, usually considerable in degree, and most often intermittent in character. Rigors are not uncommon, though by

no means constant. The patient is generally free from pain and local discomforts, but feels exhausted and very ill. The mental state is usually normal; in some cases the outlook is disproportionately optimistic. Sweats are common, especially if the pyrexia is markedly intermittent. Diarrhœa may occur. Some degree of general abdominal distension is common. The spleen may be palpable. The pulse is quickened, the pulse tension lowered, and there may be subjective cardiac disturbances related to the toxic myocarditis which is an invariable result of the main pathological process. A progressive hæmolytic anæmia is one of the most striking features in most septicæmias, both clinically and upon examination of the blood. The leucocytes vary a good deal, and their number constitutes a helpful point in prognosis: the smaller the count the worse the outlook. Loss of weight is not a noticeable symptom, except in cases which become "chronic," nor must the absence of this feature lead, of itself, to a favourable view as to the outlook. Erythemata are often seen, both diffuse and discrete, especially in cases due to streptococcus infection; they are prone to be evanescent. Purpura is not uncommon. Joint pains and swellings are also common, and these not seldom disappear without any metastatic abscess formation. Pleurisy and pericarditis are not infrequent in staphylococcus infection.

Prognosis.—The prognosis is serious in all cases of septicæmia, though less so now than formerly. This is partly because, as the result of the earlier and more extensive use of blood cultures, more cases are recognised, and partly because the exploitation of chemotherapy has added useful treatment in many instances of the disease. Of serious import are the following: rigors; the absence of signs of the local infection, the absence of a leucocytosis, rapid progression in the associated anæmia, early dilatation of the heart, vomiting, pleurisy, insomnia, and delirium or stupor.

Treatment (see pp. 16–19).

PYÆMIA

When septicæmia is complicated by the formation of multiple abscesses, or of multiple foci of tissue necrosis, the clinical condition is conveniently spoken of as pyæmia.

All pyæmic patients are septicæmic, but not all septicæmic patients are pyæmic. Some septicæmias tend to be pyæmias from the first, in other cases there is a late development of the pyæmia after a period of simple septicæmia lasting for days or, it may be, weeks. In the great majority of cases of pyæmia the primary infection is obvious.

There are three types of pyæmia according to the anatomical distribution of the primary infection in relation to the circulation.

1. *Systemic venous pyæmia.*—This is the form which is seen in osteomyelitis due to *Staphylococcus aureus*, in suppurating wounds (staphylococcus, streptococcus, *B. coli*, etc.), in suppurations of the urinary and bronchial tracts and in suppurating dermatitis and cellulitis. The metastatic abscesses form in the lungs, kidneys, perirenal tissues, joints, bones, and, less often, in the heart wall and in the brain. The symptoms are those of a severe septicæmia together with those of the disease-processes set up by the focal events just referred to. Some of the cases are of long duration, and when this is so the patient is apt to become very emaciated.

2. *Portal pyæmia* (suppurating pylephlebitis).—This is the form of pyæmia resulting from certain pyogenic infections in the alimentary tract—rectum, colon, appendix, gall-bladder and elsewhere. The infection follows in ascending fashion the radicles of the portal vein, setting up a septic thrombosis and ultimately causing multiple abscesses in the liver. The symptoms are those of a severe febrile illness with acute or subacute abdominal signs, moderate jaundice, and an enlarging liver. The diagnosis is sometimes difficult, but when indubitable the prognosis is extremely grave. The micro-organisms concerned are generally of the coliform group, or streptococcus; mixed infection is not uncommon.

3. *Arterial pyæmia.*—This form of pyæmia is seen in septic endocarditis, with which disease it is, for the most part, identical. The focus of primary infection, so far as the pyæmic process is concerned, is the endocardium, and especially of the valves, where colonisation of microbes takes place, and whence innumerable septic emboli proceed into the arterial system. Seeing that in the great majority of the cases this focus occurs on the left side of the heart the emboli, if they set up metastatic areas of infection, do so in organs and tissues supplied by the systemic vessels: spleen, brain, kidneys, limbs, etc. In the less common instances, where the endocarditic focus is on the right side of the heart, the infection being grafted upon a congenital lesion, the emboli lodge in the pulmonary vessels, producing multiple infarcts in the lung, usually with associated pleurisy.

The microbes most often causing septic endocarditis are organisms of feeble virulence (streptococci of the salivary and fæcal groups, or *H. influenza*); this fact accounts for the infrequency of suppuration in the infarcted areas occurring in this disease. When, however, the endocarditis is due to such virulent microbes as *Staphylococcus aureus* and *Streptococcus pyogenes*, abscess formation does occur in the infarcts.

Treatment. (see pp. 16–19).

TERMINAL INFECTION

Micro-organisms which are found in the tissues in the course of a post-mortem examination are related to them in four different ways: (i) They may be the primary infection leading to the disease-process which causes death. (ii) They may be present as secondary infection, in association with the primary infection, and they may or may not be largely responsible for the death of the patient. (iii) They may be present as a "terminal infection," the disease-process from which the patient suffered being not itself manifestly of microbic origin, but one tending to lower the tissue resistance to infection. The terminal infection in these cases generally, as the name implies, precipitates the lethal event, or actually causes it. (iv) They may be present merely as an agonal or sub-mortem invasion, or even as a post-mortem invasion. It is necessary carefully to distinguish between the last two of these relations. The mere isolation of organisms from certain tissues (*e.g.* the mucoid material of the middle ear) in the post-mortem room does not prove that they were present in these situations during life, still less that they were operative by way of actual infection. It is even doubtful if the cultivation of organisms from the blood of the heart, or from the cerebro-spinal fluid, after death, give evidence of infection during life,

though some authorities consider that it does. Much depends, of course, upon the conditions at the time of the investigation.

Terminal infection does certainly occur, however, in well-recognised form, and quite distinct from sub-mortem invasion. The organisms most often responsible for the condition are the less virulent strains of streptococci (*S. salivarius* and *S. fæcalis*), the coliform group, staphylococci and the tubercle bacillus. *B. proteus* and *B. aerogenes capsulatus* are also found to operate in this manner at times.

The disease-processes in which terminal infection frequently occurs are cirrhosis of the liver, granular kidney, diabetes, leukæmia and morbus cordis. There is a latent form of septic endocarditis (most often streptococcal in origin) which is also of the nature of a terminal infection. Serous membrane tuberculosis, and especially peritonitis, is quite common in cirrhosis of the liver. Many of the patients in whom this terminal infection occurs are so ill at the time the event arrives that it frequently goes undiscovered, partly because their responses to infection are feeble and partly because clinical examination is difficult.

STREPTOCOCCUS INFECTION

The streptococci form a group of micro-organisms in which the different members vary greatly in virulence. They also vary in their morphological and cultural features and in their biochemical reactions. There is, therefore, no little difficulty experienced in any effort at successful classification. Broadly speaking, there are two main groups of the microbe. (1) There is the highly virulent group called *Streptococcus pyogenes* to which the alternative name *Streptococcus hæmolyticus* is applied, on account of its property of hæmolysing when cultivated on blood-agar. (2) And there is the more feebly virulent group *S. viridans* including the variants *S. salivarius* and *S. fæcalis* of some authorities. The first type is usually seen in long and curling chains when recently isolated, and the second is usually seen in short chains of two, four, or some number of relatively few members.

S. pyogenes (vel *S. erysipelatosus*; *S. hæmolyticus*) is the causative microbe in erysipelas, in acute abscess formation, in acute cellulitis and lymphangitis, in severe operation and post-mortem infections when these are of streptococcus origin, and in the more virulent streptococcus infections complicating the puerperium, influenza, scarlet fever, and some other specific fevers.

S. viridans (*S. salivarius* and *S. fæcalis*) is found in association with pyorrhœa alveolaris, with secondary streptococcus infection in rheumatic fever, with arthritis occurring in connection with focal infections, and with most chronic and subchronic infections of streptococcal origin. The streptococci found in the heart valves, and in the blood stream in cases of subacute septic endocarditis, are for the most part of this nature.

The clinical results of streptococcus infection vary according as the infection is by the first or by the second of these types of the microbe. In infection by *S. hæmolyticus* the disease-process is usually acute and often fulminant. Septicæmia results not infrequently, and pyæmia is not uncommon. If endocarditis results from the infection and embolism occurs, the infarcts

suppurate. In infection by *S. viridans* the disease-process is prone to be chronic, or at most subacute. Septicæmia is uncommon, except in association with endocarditis, in which condition embolic infarcts proceed to coagulative necrosis, but not to abscess formation.

Treatment (see below.)

TREATMENT OF THE FOREGOING INFECTIVE PROCESSES

A. General Measures.—These include rest, ample nutritious diet, abundant fresh air, the control of fever by hydrotherapeutic means, and the maintenance of a cheerful outlook in the patient and in his medical attendant. The nursing of these "septic" patients is of great importance, and experience of similar cases is a great asset.

B. Drugs.—Formerly very intractable, many of these diseases have recently come largely under control by the use of the sulphonamide group of bacteriostatic drugs. Sulphanilamide; sulfanilamide, U.S.P.; (colsulanyde; prontosil album; streptocide; sulphonamide P.) is the more efficient drug in combating infection due to streptococcus hæmolyticus. Sulphapyridine (Degenan; M. & B. 693) is especially useful against the pneumococcus and the gonococcus. Meningococcus and coliform infections, other than the typhoid group, respond well to either. Streptococcus viridans and staphylococci, so far, have proved much more resistant to chemotherapy. Whatever preparation is chosen it should be given intensively and the oral route is to be preferred whenever possible. Foods and drugs containing sulphur (therefore eggs and salines) and strong purgatives are to be avoided during their administration. In most cases the following scheme applies for an adult: grm. 2 of the drug are given as an initial dose, followed by grm. 1 every 2 hours until grm. 20 have been administered. When rapid absorption of the drug is essential it may be dissolved in lemon juice or citric acid; if more slowly, the tablet is given uncrushed. Subsequent dosage depends upon the degree of cyanosis produced and the general state of the patient.

Cyanosis consequent on the administration of sulphanilamide may be due either to methæmoglobinæmia or to sulphæmoglobinæmia, the latter being more frequent; when following sulphapyridine (Dagenan; M. and B. 693) it is usually the result of methæmoglobinæmia (Campbell and Morgan). Methylene blue, 0·5 grm. in cachet twice daily by mouth, will diminish cyanosis due to methæmoglobin but is without effect on sulphæmoglobin, which may persist for several weeks after the drug has been discontinued. Phenacetin, and other similar drugs, which may produce methæmoglobin should not be prescribed at the same time as a member of this group; aspirin may be employed to relieve pain. Vomiting is often troublesome; it may be relieved by draughts of sodium bicarbonate solution. Occasionally it is so severe that administration of the drug by mouth must be (temporarily) abandoned in favour of the intramuscular injection of the soluble sodium salt in 10 per cent. solution. Urticaria and morbilliform eruptions may occur. Tachypnœa and hæmaturia are seldom serious complications, but the development of acute hæmolytic anæmia or of agranulocytosis calls for immediate suspension of the drug. It has been noted that a mild grade pyrexia may persist after an acute febrile illness has seemingly responded successfully to this form of

chemotherapy—a "sulphonamide fever" which settles when the drug is stopped.

To control the progressive anæmia, over and above the general measures, arsenic is perhaps the most useful remedy; it may be given conveniently as sodium cacodylate, gr. 1, once or twice daily, in the form of intramuscular injection. The writers often combine it with nucleic acid, a useful stimulant to leucocytosis, in the following formula:

℞ Sod. cacodylatis, gr. 1.
Ac. nucleici (sat.) ad min. 15.

When the leucocytosis in pyogenic infection is small, intramuscular injection of 10 c.c. of pentnucleotide may serve to increase it; the injection must be made very slowly and may be given twice in the 24 hours.

C. Surgery.—All abscesses developing in the course of a pyæmia must be drained forthwith, either by aspiration or by free incision, the former for preference and, if practicable, especially in patients who are very ill. When dental extractions are indicated in the treatment of focal sepsis, not more than two or three teeth should be extracted at one sitting; a local anæsthetic should not be employed save when regional injection (nerve block) is possible. In such a case the site of injection must be at some distance from the site of sepsis, as there is grave danger of spreading sepsis by injecting into a septic tissue. Experience proves it to be most unwise to remove teeth at the same time that the patient is undergoing any other surgical operation.

D. Transfusion of Blood.—This measure may be helpful in particular cases, especially to combat severe anæmia, or so to improve the patient's general condition that he may be in a better state to derive benefit from other remedies.

E. Specific Therapy.—Measures which may be used to combat the infection by way of immune therapy are, it goes without saying, of much greater theoretical importance than those which act non-specifically. Unfortunately our knowledge of efficient specific remedies grows very slowly, and there are many gaps and guesses in it. All the same, careful consideration should be given in every case to the nature of the infection, and to the question if some form of specific treatment, whether by immune serum or by vaccine, or by both, may not be of service.

1. *Streptococcus Infection.*

(*a*) *Hæmolytic streptococcus infections.*—These include acute septicæmia, puerperal fever, certain complications of scarlet fever, erysipelas and acute cellulitis, in which "scarlet fever" antitoxin serum and sensitised *Streptococcus pyogenes* vaccine are the agents now chiefly used in immuno-therapy. Scarlet fever antitoxin has largely replaced the original *Streptococcus pyogenes* antiserum, but if no benefit is observed after the use of the former remedy recourse should be had to the latter. Concentrated serum should be given as early as possible: 10 or 20 c.c. intramuscularly, repeating 10 c.c. eight hourly as need be. Sensitised vaccine is made from strains of *S. pyogenes* recently isolated from several sources, and may be given in doses of 100, 250 and 500 millions subcutaneously on three successive days.

(*b*) *Streptococcus viridans infections.*—These are not amenable to serum

treatment. These organisms are frequently concerned in the ætiology of focal sepsis. When pyorrhœa alveolaris is the cause of focal infection, the material from which the vaccine is prepared is to be taken from the apex of an infected tooth immediately after extraction, and not from pus lying about the neck of the tooth which is always the nidus of secondary infections, erroneously thought to be causative of the condition. The initial dose may well be 5 million cocci, followed at intervals of 7 to 10 days by gradually increasing doses—10, 25, 50 and 100 million cocci. Even larger doses may be profitably given should no " reactions " occur.

Fibrositis, arthritis and allied conditions.—In embarking on the treatment by vaccine therapy it has to be realised that such treatment will be brief or long according to the time the lesions have existed. In this connection, moreover, it should be borne in mind that even if the lesions are not of long standing, the toxæmia leading to those lesions may be of much longer standing than at first suspected.

Recent cases of infective arthritis only rarely present themselves for treatment, but there should be an increasing tendency in this direction.

2. *Staphylococcus Infections.*

Chronic local infections.—These consist of boils, carbuncles, pustular acne, onychia, sycosis, otitis media (sometimes), eczema (sometimes), ciliary blepharitis, suppurating Meibomian cyst and certain discharging sinuses. Furunculosis and certain other staphylococcal infections were the first to be treated systematically by Wright's method of specific inoculation, and, as a class, these infections yield, with care, fairly satisfactory results.

A guarded prognosis must, however, be given in connection with each of the other forms of staphylococcus infection. And in all the cases care must be exercised to see that the general points in treatment are receiving attention. If these be omitted, failures will frequently be met with in those cases in which the infective factor is not very dominant. In acne, for example, it is unlikely that vaccines alone will affect a cure if local measures be omitted. Here, as always, the inoculations must be regarded as adjuncts to the general programme of treatment, not as a substitute for it.

In the case of suppurating wounds or sinuses, vaccine treatment should never be expected to take the place of efficient drainage, which must in all cases be secured in the first instance.

In the matter of *dosage* most workers agree in using a dose of 100 million in beginning the treatment of a straightforward case. If improvement follows, this is succeeded by doses of 250 to 300 million with intervals of 8 to 10 days. Relapses are quite common, and require a good deal of careful management. Either the doses are not sufficiently large, or the inoculations are repeated too frequently. Each case must be considered on its merits. In the experience of the writers there is often a tendency to stop the treatment too early. It is often of value to " space " the doses more widely as the treatment proceeds.

In the treatment of acne, a similar plan may be followed, or a mixed vaccine of staphylococcus and the " acne bacillus " employed. In sycosis the response to these doses is only satisfactory if the case is treated early. If it is of some standing, and much induration is present, the vaccine should be tentatively increased to 2000, 5000 and even to 8000 million cocci. The same rule applies to many cases of chronic acne. Once more, let it be urged

that it is courting disappointment to neglect necessary methods of treatment when dealing with these chronic skin infections.

It has become customary to employ stock vaccines in the treatment of furunculosis and other staphylococcus infections, and, as staphylococci appear to differ little in the matter of strains, the success of this convention justifies the practice. If, however, success is not attending the treatment, an autogenous vaccine should in all cases be obtained. This is perhaps more important if the infection is due to *S. aureus* than if to *S. albus*.

Acute local infections.—A single dose of vaccine certainly tends to cause an acute boil or carbuncle to abort, but it should be administered early to secure this effect. The dose chosen is usually 1000 million of mixed staphylococci. Care must, of course, be taken to give no dose of this size in the presence of any constitutional symptoms which may indicate a general infection. But a general infection may quite probably be avoided by the above-mentioned prompt treatment. In the case of boils of the external auditory meatus and other very painful situations, the more rapid development and consequent resolution of the lesion following administration of a vaccine are of considerable advantage.

Poisoned fingers and acute abscesses due to staphylococcus infection require much smaller doses. They are best treated by (say) 50 to 100 million cocci, with 3 or 4 days' interval.

ERYSIPELAS

Definition.—An acute specific disease, due to infection of the skin by *Streptococcus pyogenes*, leading to local dermatitis and constitutional symptoms, of which fever and toxæmia are the most prominent.

Ætiological Factors.—Infection by *S. pyogenes* is certainly the essential factor. The more carefully the cases are examined and the patients questioned the more certain it becomes that in the great majority of them some abrasion, it may be very slight, is present in the skin at the site of infection. This abrasion may be an actual wound, whether of a surgical operation or not. More often it is less apparent—a scratch, an insect bite, the chafing of a foot by a badly fitting shoe, etc. Contact by the human hand during the infliction of these slight injuries is not uncommonly a feature in the case.

Bad hygienic conditions seem to contribute to the incidence of the disease, such as defective sanitation and ventilation in public institutions. Formerly the disease was rife, almost epidemic, in hospitals, and chiefly amongst the surgical patients. During the puerperium a woman is prone to erysipelatous infection.

The disease is said to have a seasonal incidence (January to May), and Newsholme showed that the curves of its prevalence conformed somewhat to those of scarlet fever and acute rheumatism. We do not know, however, the reasons for this.

The disease is more common in women than in men, perhaps because of the puerperal cases. Alcoholism is a great predisposing factor. Gout is another factor rather commonly present.

Symptoms.—There is an incubation period of some 2 to 5 days. The onset is usually abrupt, often with a rigor (or a convulsion in little children)

certainly the most important, feature of gonococcus infection is its obstinate persistence. This organism is, relatively to many others, responsible for few deaths as the direct result of acute infection, but this low mortality ratio is compensated by a high degree of morbidity incidence. Once the invasion of gonococci has led to definite tissue infection, this is prone to become very intractable, resisting the most persevering and thorough efforts at defeating it. Gonococcus infection is too often measured by years rather than months, though there are oft-times intervals of comparative freedom from toxic effects upon the infected organs. Such a lesion as acute iritis, for example, may appear in the subject of old gonococcus infection, several years after the primary invasion, and the evidence that the inflammation is due to this source may be unimpeachable. The writer has known this to happen fourteen years after the primary urethritis. But it is sometimes very difficult to exclude a recurrence of the initial infection.

Once the inflammatory response to infection has passed the urethral stage, it is often very difficult to obtain direct bacteriological evidence of the nature of a suspected gonococcus infection. The number of organisms concerned may be small, they are often deeply embedded in the tissue spaces and cells, and they may not be shed into any effusions or secretions that chance to be available for clinico-pathological investigation. As yet, the indirect diagnostic methods (agglutination, complement fixation, etc.) are scarcely of sufficient trustworthiness to supply the data left lacking by the negative direct bacteriological results referred to.

Secondary infection, especially by staphylococci, streptococci and diphtheroid organisms is very common.

Clinical Results of Gonococcus Infection.—These may be considered under three headings: the results of the primary infection, the results of the zone of immediate spread, and the results of general dissemination.

(i) *The results of the primary infection.*—These are acute and chronic urethritis (with gleet); cervicitis; and conjunctivitis. These lesions do not come under consideration in a text-book of medicine.

(ii) *The results in the zone of immediate spread.*—These include peri-urethritis (and abscess), prostatitis, epididymitis and vesiculitis in the male; salpingitis with salpingo-ovaritis in the female; and cystitis in both sexes. In both sexes, again, the peritoneum may become infected locally, a much more common and important event in females than in males, as might be expected for anatomical reasons. Indeed, in women, varying grades of pelvic peritonitis, with plastic inflammatory changes, constitute perhaps the greatest bane of gonococcus infection, both from the physician's and the surgeon's point of view. Chronic ill-health, adhesions that permanently handicap the functions of the pelvic viscera, and acquired sterility are amongst the disabilities accruing therefrom. In the male, late results of infection are scarcely less serious by way of nemesis: urethral stricture, chronic prostatitis, "ascending" pyelitis and secondary colifo~m infection of the urinary tract.

(iii) *The results of general blood infection.*—These may be subdivided into a true septicæmia and pyæmic manifestations.

(*a*) *Septicæmia*, though rare, has been definitely established clinically and clinico-pathologically, both in America (Thayer, Blumer, Ahmann) and in England (Horder). Endocarditis, of a progressive and "ulcerating"

form, is present in most of the cases, and, though recovery has taken place in one or two known instances, the disease is generally lethal. Diagnosis turns upon the isolation of the organism from the blood stream in a case presenting the clinical features of septicæmia.

(*b*) ***Pyæmic manifestations.***—Of these the most important is ***gonorrhœal rheumatism,*** with associated arthritis, fibrositis, teno-synovitis and allied lesions (see p. 1335). Gonorrhœal rheumatism must be considered to be a form of gonococcus pyæmia, at least when seen in its acute and sub-acute types. The organism has been recovered from the affected joints in a large number of the cases, and in a few from the blood stream as well as from the joints. ***Spondylitis deformans*** has been traced to (old) gonococcus infection in a considerable proportion of cases.

Pericarditis and ***pleurisy*** have both been described as remote results of gonococcus infection.

Iritis, already referred to, is prone to be of the recurrent type. It is often ascribed to syphilis when it is much more probably of gonorrhœal origin.

Treatment.—In acute infections the use of sulphapyridine has proved very successful. In chronic infections the same remedy should be given a thorough trial, but the results are much less favourable. Antigen therapy may be cautiously attempted.

COLIFORM BACILLUS INFECTIONS

Continued and extended observations, made possible by the introduction of newer differential bacteriological methods, have resulted in the recognition of a large and important group of bacilli, called the coliform group, including members which differ as widely in pathogenicity as these two originally described bacteria, but also including the organisms of bacillary dysentery, the paratyphoid organisms, the various bacilli causing "food-poisoning," such as the Aertrycke bacillus, *B. enteritidis* of Gaertner, *B. suipestifer* and others.

Modes of Infection.—In health, coliform bacilli are confined to the intestine. The modes of infection of parts of the body other than the bowel are at times very apparent, at others obscure. Of any particular tissue there are three possible routes of infection: (1) The *direct* route, that is, by the immediate transference from the bowel to the infected area; (2) by the *lymphatics*; and (3) by the *blood stream.* In some infections, *e.g.* of the gall-bladder, pericolic tissues, pelvic cellular tissue, etc., the direct route is no doubt the one generally followed. Of the two indirect routes, however, some doubt exists as to the more likely one in certain cases, such as infection of the urinary tract especially; in some instances of this latter important condition it is clear that invasion takes place again, directly, through the urethra. The cystitis which still occasionally follows the use of the Catheter illustrates this; and the greater frequency of coliform bacillus cystitis in little girls than in little boys has been adduced in favour of this route. In the acute pyelitis complicating or following typhoid fever, it is highly probable, though not certain, that infection proceeds via the blood stream to the kidney, and thus to the pelvis. But in those acute primary infections of the urinary

tract, which are so common in both sexes, the mode of entry of the bacillus to the kidney pelvis is problematical.

Sites of Infection.—The sites of infection by coliform bacilli are very numerous. Mention will only be made here of those which form the basis of important disease-processes which demand recognition and treatment in practice.

1. The *bowel* itself may be the site of infection. This may take place (*a*) because the infecting strain of coliform bacillus has absolute pathogenic qualities; or (*b*) because the virulence of one or more of the usually saprophytic strains is increased; or (*c*) because the resistance of the mucosa is lowered by chemical or physical changes or by infection by another pathogenic microbe. From one or more of these factors acute or chronic *enteritis*, *entero-colitis*, or *colitis* may ensue. Gaertner bacillus poisoning, the result of eating contaminated food, is an important instance of (*a*), and perhaps also of (*a*) combined with (*c*). Some cases of *cholera nostras* appear to be due to coliform bacillus infection, and probably most sporadic cases of acute colitis. There is no great obscurity attaching to these infective processes. In a consideration of many cases of *chronic colitis*, however, the exact rôle of coliform bacilli is very obscure indeed; and this, even when we exclude a large number of cases of bowel defect to which the name *colitis* should never be applied at all. It is probable that many of the patients said to be suffering from *intestinal intoxication* are in reality the subjects of subinfection by coliform bacilli. But at present our criteria for judging accurately of such a condition are lacking. Mere qualitative bacteriological investigations of the fæces in such cases yield at most presumptive evidence, and quantitative investigations take us very little farther. We await some method of estimating tissue infection by the coliform group more constant than agglutination, which is rarely present in chronic cases, and is, therefore, of little use as a guide.

2. *Gall-bladder sepsis* is closely associated with coliform bacillus infection It is commonly held that subinfection of the gall-bladder by this microbe is one of the important factors in the evolution of cholelithiasis. However this may be, it is certain that coliform bacilli are frequent infecting agents in *cholecystitis*, both acute and chronic. The fact harmonises with the known frequency of gall-bladder infection during typhoid fever. The association of coliform infection of the urinary tract and of the gall-bladder is of common occurrence, and the removal of a gall-bladder which is the seat of chronic inflammation may react favourably upon the coincident urinary infection,

3. *Appendix inflammations*, *diverticulitis*, *pericolic suppuration* and local peritonitis complicating intestinal conditions, are all of them associated with coliform bacillus infection, and in many instances with this alone.

4. The *urinary tract* is infected with great frequency, with how great frequency we are only now realising, as the result of systematic cultivation of the urine in doubtful cases of the condition, and in obscure cases of illness in which no such condition is at first suspected. It is important to note, however, that the mere presence of coliform bacilli in the urine—it is assumed that catheter specimens only are being dealt with, or that, when this is not the case, there is good evidence that the bacilli actually come from the

bladder—does not establish an actual urinary tract infection. *Coliform bacilli* in the urine may signify one of either of the following conditions: (*a*) The elimination of the bacilli from the body through the kidney, without infection either of this organ or of the urinary tract; this process is usually of brief duration, and may be intermittent. (*b*) The excretion of bacilli (with pus) from an infected kidney or from some focus of infection adjacent to the urinary tract (prostate, urethra, pericolic tissues). (*c*) True infection of the urinary tract (pyelitis, pyelonephritis, cystitis, pyelo-cystitis). (*d*) Bacilluria.

Concerning (*a*) and (*b*) no more need be said in this place, but (*c*) demands more consideration.

Coliform Bacillus Infection of the Urinary Tract.—The cases met with may be conveniently described as falling into three groups.

(i) *Acute cases.*—In the majority of these cases the infection appears to arise in the pelvis of the kidney; some are undoubtedly vesical in origin; in not a few it is uncertain where the infection begins. The disease is at times quite fulminating in its acuteness, being ushered in by rigors, high fever (103° to 105°), delirium and great drowsiness. More often the symptoms are abrupt and severe, but not alarming. There may be pain and tenderness in the loin, and one or other kidney may be tender under bimanual examination. But in more cases than not there is a striking absence of both physical signs and focal symptoms, so that, unless the existence of the disease is borne in mind, and the urine is examined carefully, the patient is thought to be suffering from "influenza."

In those cases in which the bladder is, from the first, markedly affected, symptoms of *dysuria* are present—frequency, pain and strangury. Such symptoms draw attention, of course, to the nature of the process.

The *urine* shows a great range of variations in its features. There may be a fairly frank *hæmaturia*, a fact which is not so widely known as it should be: coliform bacillus infection is the explanation of a large number of obscure cases of hæmaturia. The amount of pus is very variable—it may be very considerable, or it may be represented only by leucocytes seen on microscopic examination. In very severe cases portions of the bladder mucosa may be shed in the form of sloughs, but this is uncommon. Like the pus, the bacilli vary greatly in the degree to which they are present in the urine; in some cases they are so abundant as to constitute by far the greater part of the total sediment. The colour and amount of the urine depend upon the degree of pyrexia and the amount of fluid ingested. Constipation is the rule, the tongue is generally covered by a creamy fur, and anorexia is common. As in so many acute coliform bacillus infections, the mental state tends to depression.

The disease is often a strikingly dramatic one in children; it is one of the few conditions which may be associated with a rigor, and there is a maximum of febrile reaction with lassitude and even stupor, and a minimum of serious effect upon the vital organs. It is not very uncommon to see a temperature of 105° or 106°, with big intermissions; the child is very ill during the pyrexial stage and comparatively well when the temperature falls. Marked drowsiness, even stupor, may occur; such a condition, indeed, should raise a suspicion of this infection in the absence of signs of meningitis. The disease is not very uncommon even in babies.

The course of the disease varies much. Prompt recognition of its nature, leading to appropriate treatment, usually results in defervescence and the disappearance of pus and bacilli from the urine in 7 to 14 days. But some of the cases last many weeks; it is fair to say that this is not seldom due to failure to diagnose the condition, or to employ efficient measures of treatment.

Relapses are very common even when, with chemotherapy, the urine is rendered sterile and the symptoms are relieved. Of *complications*, *prostatitis* is perhaps the one most often seen; *epididymitis* occurs less often, but is a very definite condition; *urethritis* may occur; *pyelonephritis*, especially in young children, may be the precursor of renal failure in later life. It is interesting to record that epididymitis may be the first symptom of the disease. This has, in the past, been frequently mistaken for tuberculosis.

(ii) *Recurrent cases.*—A not uncommon type of case is that in which symptoms of acute or of subacute infection occur at intervals over a number of years, the condition of the patient and of the urine being natural between the attacks. Recurring hæmaturia, thought to be due to acute nephritis, to tuberculosis or to calculus, is sometimes due to this condition. The probable source of these re-infections in any individual case is the colon.

(iii) *Chronic cases.*—These are either (*a*) the sequelæ to acute attacks that have never completely resolved; or (*b*) they arise insidiously; or (*c*) they follow instrumental procedures or operations upon the urinary tract; or (*d*) they complicate mechanical defects, such as stricture (acquired or congenital), enlarged prostate, and hydronephrosis; or (*e*) they occur as secondary infections in cases of renal or vesical calculus or of tuberculosis.

The symptoms in these chronic cases vary greatly. In one group it is the general toxic state that is the main feature—a sallow complexion, loss of tone, a low blood pressure, colon dyspepsia, headache and backache. In another group the local symptoms predominate—increased frequency of micturition, which may be extremely trying, pain during or after the act, and referred pain and discomfort in the vesical zone. In a third group there is little or no interference with health, general or local; but a vivid realisation of the existence of the condition troubles the patient's mind, leading sometimes to a state of bladder neurasthenia.

The urine in chronic infections shows as much variety as do the symptoms. The characteristic "fishy" odour is rarely absent; the reaction is generally acid, but infection by *B. proteus* renders the urine strongly alkaline; the amount of pus present may be very little or may be considerable, but the degree to which the patient is troubled by no means corresponds to the degree of pyuria; mucus is in excess; bacilli are constant and, like the pus, are very variable in quantity. Hæmaturia is uncommon in chronic infections, but it is easily induced by instrumental investigation, as are also "flares-up," of the chronic state, with the production of rigors, high fever, severe malaise and relative anuria. For this reason, methods of differential diagnosis which do not involve instrumentation should be employed before the patient is subjected to cystoscopy or ureteric catheterisation.

Bacilluria.—This term is properly applied to a urine which is loaded with bacilli, but in which there is no pus, or, at most, a few leucocytes seen on microscopic examination. It is a state of kidney elimination of bacilli rather than a condition of bacillary infection. It is usually of short duration. The appearance of the urine is characteristic: shimmering when agitated

and viewed by transmitted light. The smell already referred to as so typical of colon bacillus urinary infections is usually present here also.

OTHER SITES OF COLIFORM BACILLUS INFECTION.

(i) *The uterus and Fallopian tubes* are sometimes the site of infection, as in puerperal sepsis; but the infection is then usually a mixed one, with streptococci.

(ii) Some situations quite remote from the bowel are now and again infected by coliform bacilli—the *middle ear*, the *pleura*, the *bronchial tract*, *bones* and *joints*. Infection of the middle ear occurs as the result of impure water in swimming-baths.

B. COLI SEPTICÆMIA, unless it occurs as a terminal event, in which form it is not at all uncommon, is rare. When it does occur, however, it is by no means always fatal. Septic endocarditis, due to coliform bacilli, is rarer still; the only cases coming under the writers' notice have been of the nature of a terminal infection.

Treatment.—The treatment of cases of coliform bacillus infection may be considered under three heads—general, local and specific measures.

1. GENERAL MEASURES.—In all acute cases the patient is kept in bed, so as to ensure rest and warmth. Both of these are essential, and even in chronic cases it is of great importance to avoid cold and fatigue. As the *bowel* is the source of nearly all the infections, attention to it is paramount. It is quite impossible to say in how many seemingly unlikely cases the intestine, and especially the colon, will be found to give the clue to treatment, provided the possibility be borne in mind. Especially is this the case in acute and subacute cases. To correct constipation is not enough—constipation may not even be present—efforts must be made to change the bowel contents in such a way that they are no longer so good a nidus for growth of the bacillus. This is best attained by a *diet* which is low in total protein content; meat, eggs and raw milk are excluded entirely; junket, whey, buttermilk and cream being allowed. The following articles of food are also allowed: macaroni, boiled rice, raw and cooked fruit, salads, and lightly cooked green vegetables, jams, marmalade, honey, cold fat bacon and ham, and chicken and white game occasionally. Wholemeal bread and oatmeal porridge are recommended. On such a diet the consistency of the stools soon improves, and they lose their ill-digested appearance; as also mucus and sandy deposit, if these were present. They also become much less offensive to the smell. Plain drinks are encouraged—preferably between meals. If the case be acute, with considerable pyrexia, the practitioner generally considers milk the staple food indicated; but even in these cases it is often possible to demonstrate rapid progress so soon as milk is disallowed.

The choice of aperients is of great importance. In acute cases, calomel is very useful combined with salines, provided the patient is not taking sulphanilamide. In chronic cases, the most helpful form of laxative is of the paraffin and agar-agar type (emuls. paraff. liq. cum agar., B.P.C.), supplemented if necessary by a compound aloin pill.

A course of *high colonic irrigations*, following the Plombières method, is indicated if mucus persists in the stools despite the above measures.

In acute cases of infection of the urinary tract with high fever and dysuria, full doses of *alkalis* (sod. bicarb. and pot. cit.) combined with tincture of hyoscyamus are helpful for the first 3 or 4 days. Bicarbonate of soda may be

added to barley water and citrate of potash to lemonade; the patient is encouraged to drink freely of these fluids, at least 3000 c.c. (4 pints) in the 24 hours. By the time the urine has been strongly alkaline for 3 days the temperature will most likely have fallen: indeed, if the pyrexia persists unabated in such circumstances search should be made for some cause other than a coliform infection of the urinary tract to explain it. Now is the time to limit the fluid intake for an adult to 1000 c.c. (1½ pints) in 24 hours, and to give full doses of *sulphanilamide*. An initial dose of 2 gm., followed by 1 gm., two-hourly by day and four-hourly by night (*i.e.* ten doses totalling 11 gm. in 24 hours). This dosage is maintained for 48–72 hours and then halved for the next 3 days, by which time the urine will probably be sterile. In elderly patients with chronic cystitis the infection may be kept in check with the aid of 0·5 gm. three times a day on four days a week. (For other details of sulphonamide therapy, see pp. 16–17.)

If for any reason it is judged unwise to administer sulphanilamide (sulfanilamide U.S.P.), or if on trial the patient proves intolerant thereof, *mandelic acid* should be tried; with this drug also the fluid intake must be restricted. Salts of mandelic acid, such as ammonium mandelate, gm. 3 (grs. 45), given by mouth every 6 hours, diminish the growth of coliform organisms, provided the urine is kept highly acid, that is the *p*H between 5·0 and 5·5. Acid sodium phosphate, in doses of gm. 2 (grs. 30), should render the urine sufficiently acid; to determine that this is so, to half an inch of urine in a test tube add a few drops of methyl-red solution: the resulting colour should be pink. Each specimen of urine is so tested, and the dose of acid sodium phosphate adjusted accordingly. The treatment may have to be maintained for 7–10 days; recrudescence or recurrence of infection is not infrequent and demands a further course. Mandelic acid therapy is contra-indicated in all cases of renal failure, as the accompanying acidosis may cause a rapid rise in blood urea.

If these measures fail the *hexamine group* will do good in proportion as the infection is focused in the urinary tract and in the renal pelvis rather than in the bladder. To get the greatest service from hexamine in urinary tract infections it is best to keep the urine acid, and for this purpose acid sodium phosphate is serviceable. It is well to change the hexamine (gm. 0·3 to 1·6 or grs. 5 to 25 well diluted) for one or other of its derivatives now and again, reverting to the hexamine again later: hexamine sodium acetate (cystopurin), hexamine with citrate (helmitol), hexyl-resorcinol (caprokol). In chronic cholecystitis much larger amounts of hexamine have been employed, up to gm. 14 (grs. 200), given in ten equal doses in the 24 hours; it is essential that the reaction of the urine should be maintained alkaline lest hæmaturia and strangury ensue.

2. Local Measures.—Local suppurations are, of course, dealt with surgically. Reference has already been made to associated disabilities in some cases of urinary infection which also require surgical treatment. In bowel infections a useful adjunct in treatment is to endeavour by means of posture, massage and efficient supports to improve matters if enteroptosis be present.

3. Specific Measures.—There remains to be discussed the use of bacillary vaccines. These should always be regarded as supplemental to, rather than substitutions for, the scheme of therapeusis outlined in (1) and (2). In acute

cases vaccines are not indicated. In chronic cases, if vaccines are employed they should be given a good trial; it may be that a streptococcus is associated with *B. coli*, in which case an autogenous vaccine of this organism should also be given. Sometimes the good effects are striking, at others little or nothing is achieved. *The vaccine should invariably be autogenous in nature.*

TUBERCULOSIS

Definition.—Infection of the body by *Bacillus tuberculosis*, leading to lesions which are characterised by tubercles, microscopic or macroscopic, themselves undergoing changes leading to caseation, necrosis, ulceration and calcification, and having in close association with them varying degrees of fibrosis. The lesions of tuberculosis form the histological and anatomical basis of a large number of diseases which differ according to the organs affected, the extent of the lesions and the degree of resistance to infection shown by the tissues.

Ætiology.—The Bacillus Tuberculosis (Koch, 1882).—This is regarded by many bacteriologists as a member of the Streptothrix group of micro-organisms; that is to say, the bacillus found in tubercular lesions is considered to be the bacillary form of an organism allied to the Streptothricæ. The other phases in the life-history of the micro-organism are not met with in the actual disease-process, but may be demonstrated in old cultures and in certain experimental lesions. This view of the essential nature of the tubercle bacillus harmonises with our knowledge of its great power of resistance to various destructive agents; it also explains many of the tissue changes occurring in the disease, the latency seen in many cases of infection and the chronicity of many others. The bacillus measures 1·5 to 4 μ in length as an average, is slender, and when isolated from secretions or tissues is usually bent or curved, and tends to lie in small groups. It is "acid-fast" in its staining reactions, allowing of easy recognition; but it grows very slowly outside the body, requiring special media for the purpose of culture. The bacillus is capable of living for several months in dried sputum, and may be cultivated, or may be made to cause disease in susceptible animals, when obtained from the dust of ordinary living-rooms. The gastric juice does not destroy the bacilli, nor does the process of decomposition going on in dead tissues over a period of many weeks. The clinical importance of these facts is obvious. In contrast with these examples of resistance may be mentioned the fact that direct sunlight has a rapid lethal effect upon the micro-organism; so also has a solution of carbolic acid, of strength 1 : 20.

Known differences exist between the bacillus causing tuberculosis in man, in cattle, and in birds respectively. The *avian* form appears to be of little importance. The *bovine* type would appear to cause about 10 per cent. of all cases of tuberculosis in man. In children, the bovine type is found relatively more often. The *human* type of bacillus is less virulent to cattle than is the bovine type, but—though this cannot be made the subject of experiment—the bovine type is probably as virulent to man as is the human type. Of young children dying with primary abdominal tuberculosis, the fatal lesions, in nearly half of all cases, have been referred to the bovine bacillus. Again, in both children and adolescents suffering from tuberculous

adenitis, a large proportion of the cases examined could be referred to the bovine bacillus. Lastly, in lupus, about half of all cases appear to be referable to the bovine type of *B. tuberculosis* (Royal Commission on Tuberculosis).

Sources of Infection. —There are two great *sources of infection* of tuberculosis—phthisical sputa and tuberculous milk. Sources of minor importance are urine and fæces containing the bacilli as the result of active lesions in the urinary and intestinal tracts, and the flesh of tuberculous cattle eaten as meat. But the main source of the infecting bacilli of the human type is undoubtedly dried human sputa. Nuttall found that from 2 to 4 billion bacilli were expectorated in 24 hours by a patient whose phthisis was only moderately advanced. These bacilli are scattered freely in dust when the sputa become dried, and they lie about the surface of the patient's body, or they are projected directly into the air along with particles of moisture when patients cough or sneeze or even speak loudly.

Of the *bovine* type of bacillus it is probably not an exaggerated estimate to say that some 25 per cent. of all dairy cows in this country are tuberculous. In New York, Hess found tubercle bacilli in 16 per cent. of the 107 specimens which he examined.

Modes of Entrance of the Bacillus into the Body.—Although there are some other *channels and modes of entry* that have theoretical interest, the two chief ways by which the body is infected are undoubtedly ingestion of the bacilli by the alimentary canal and inhalation of them by the respiratory organs. Compared with these two, all other avenues of infection are trivial.

1. *Ingestion.*—Infection through the *intestinal mucosa* is considered to be the most common mode of production of tuberculosis in children, the main source of the bacilli being contaminated milk. This conclusion has the confirmation of clinical and post-mortem observations, as well as the support of experimental work by Behring, Calmette and others. Ghon has adduced facts which suggest that, even in little children, infection may be much more often brought about by inhalation than was formerly thought. Ghon's observations have been confirmed by Eastwood and Griffith, and by Canti.

Another channel of entry by ingestion is the *tonsils*; tubercle bacilli have been demonstrated by Hugh Walsham and others to pass through the tonsillar tissue to the cervical lymph glands. The tonsils are themselves rarely affected.

2. *Inhalation.*—Primary infection by the route of the air passages is difficult of proof and, indeed, some authorities regard it as negligible compared with (1). The great frequency of respiratory tuberculous lesions, however, and the incidence and mortality-ratio of pulmonary tuberculosis in ill-ventilated districts and buildings, are points difficult to explain satisfactorily without the assumption that in the majority of these cases infection takes place by inhalation. The sequence of events is considered to be somewhat as follows. Finely divided droplets carrying the bacillus are inspired during childhood. The bacilli are conveyed by the lymphatics to the glands which become inflamed but, later, heal. A few bacilli escape the gland filter and are redistributed by the blood stream in diffuse fashion in the lungs. Foci so produced mostly heal, but those near the apex do so less readily, and come to constitute the lesions of chronic pulmonary tuberculosis.

The statistics relative to contagiousness in tuberculosis institutions are conflicting.

3. *Inheritance.*—Inheritance of tissue-susceptibility to infection by tuberculosis is a definite fact. But inheritance of tuberculosis is problematical, if by this is meant the transmission of tubercle bacilli in the spermatozoön or in the ovum. In the few cases of "congenital tuberculosis" that have been authentically described, the transmission has probably been from a diseased placenta to the blood of the fœtus.

4. *Skin inoculation.*—This is of little more than theoretical interest. Post-mortem warts (*Verruca necrogenica*) are occasionally of tuberculous origin. Czerny, the surgeon, reported a couple of cases of inoculation during skin transplantation.

Among *other ætiological factors* the chief is undoubtedly the *inherited tissue-susceptibility* to infection already referred to. The exact nature of this susceptibility is not known, but its existence is one of the cardinal facts of clinical medicine. *Sex* seems not to be a factor. *Racial differences* in susceptibility are noticeable, though the distinction between morbidity-incidence and mortality-incidence must be made here—the former is high in the Irish, the latter in negroes. In the Jews, though the disease is common, the mortality-incidence is low. *Trauma* is definitely known to induce pulmonary infection, or, perhaps it should be said, pulmonary spread of the disease. All *occupations* tending to inhalation of dusty particles, and those which keep the workers in ill-ventilated and badly-lighted rooms and places, increase the liability to tuberculosis, especially of the pulmonary kind. If *bad economic conditions* concur with either of these the liability is increased. *Debility,* whether the result of acute illnesses, or caused by pregnancy, parturition, prolonged lactation, or exhausting modes of life generally, increases a natural susceptibility, and gives an acquired susceptibility when no hereditary weakness is present. Tuberculosis is not infrequently a *terminal infection* in such diseases as diabetes, cirrhosis of the liver, leukæmia and chronic nerve affections such as tabes dorsalis, etc. *Recurring and chronic respiratory catarrhs* seem at times to lower the local resistance to tuberculosis, though it is often matter for comment that so many patients with emphysema, asthma and chronic bronchial catarrh live for many years without developing pulmonary tuberculosis, provided they inherit no special tissue tendency to infection by the bacillus.

Incidence and Mortality.—The healthy human body is considered to be relatively immune to infection by the bacillus of tuberculosis. Against this statement, however, it must be said that, whether from the ubiquity of the causative germ, or from one or more of several factors enumerated in the preceding paragraph, some 70 to 80 per cent. of all adult cadavers carefully examined in Western countries show lesions due to the bacillus. It is said, too, that one-seventh of the whole race dies as the direct result of tuberculosis. The disease is one of "low resistance," this being the result either of inherited predisposition or of acquired loss of resistance, or of both of these.

The results of infection are of great variety and of all grades of intensity. The variety depends upon the tissues affected, and the route of spread of the infection. The intensity depends upon the degree of relative virulence shown by the bacillus, and the amount of resistance shown by

the patient. Tuberculosis may exist without appreciable disturbance to health, and the lesions produced may be commensurate almost with the whole length of a patient's life. On the other hand, the infection may cause an illness of the most severe character, killing the patient in a few weeks. The results of infection are described elsewhere in this book under appropriate headings, but *general infection* leading to the condition termed general tuberculosis is included in this article.

Diagnosis.—The Isolation and Recognition of the Bacillus.—In all doubtful cases of tuberculosis this is a point of vital importance. Clinical evidence of the existence of the disease, however complete it may seem to be, must never lack the confirmation of bacteriological proof, whenever this is possible. ("Physical signs are the signs of conditions, not of diseases.") Seeing that the only radical proof of the existence of the disease is the demonstration of the bacillus in material derived from the patient, attention must first of all be directed to this investigation. By comparison with this demonstration, even the most definite "reaction" to one or other of the tuberculin tests, or the most strikingly positive result with the complement-fixation method, is untrustworthy. It behoves the practitioner, therefore, to watch jealously for any material that may be available for bacteriological use, and to be quite certain that such material is not obtainable before falling back upon indirect clinico-pathological evidence (see below) to support the diagnosis.

In cases of suspected phthisis, every effort must be made to secure sputa, and it may be necessary to check a habit of swallowing expectorated material. The single, isolated plug of mucus, which is often expectorated in the early morning, should not escape attention. In little children, sputa, as such, are usually absent, but if vomiting occurs in association with lung disease the vomit should be searched for fragments of sputa. In suspected disease of the kidney or urinary tract, the urine must be collected carefully and submitted to examination. Cases of *albuminuria* or of *hæmaturia*, in which there is not clear evidence of diffuse nephritis, should raise the question of tuberculous disease of the kidney. The fæces should be scrutinised in doubtful tuberculosis of the lung, peritoneum or bowel. If any *puncture-fluid* is obtainable—as from the pleura, the spinal theca, or a joint—this is valuable for investigation in any patient suspected of tuberculosis.

The methods of dealing with these materials are not difficult, though they require thoroughness and patience when the bacilli are present in scanty numbers. The very different significance to be attached to a positive as against a negative result must never be lost sight of; the former affords proof of the existence of a tuberculous lesion, the latter gives at most a presumptive evidence against it.

In dealing with *sputa*, the original carbol-fuchsin method of Ziehl-Neelsen should first be tried. If the results, after carefully searching 3 or 4 films for half an hour, are negative, the sputa should be shaken up thoroughly with ten times its bulk of carbolic acid, of strength 1 : 20, allowed to sediment, the supernatant fluid run off, and films made of the residue. If the sputa are seen to be thin and watery, this method is likely to give a negative result. If so, one of the digestion methods may be used—either pepsin and hydrochloric acid, or "anti-formin." The use of the last-named substance, consisting of a mixture of equal parts of bleaching powder solution and a 15 per

cent. solution of caustic soda, is found by some workers to give excellent results. An amount of this fluid, equivalent to about one-fifth of the bulk of the sputum, is mixed with it, allowed to act for 3 to 4 hours, the mixture centrifugalised, and the deposit dealt with by one of the staining methods in ordinary use. The bacilli are, by the disintegrating action of the "anti-formin," isolated from the albuminous vehicle and concentrated in the deposit.

Urine is best dealt with by the carbolic acid method (*v.s.*), subsequent centrifugalisation, and staining of the deposit. The smegma bacillus (also acid-fast), which may be present if the specimen has not been obtained by catheter, is differentiated by allowing the stained films to remain in alcohol for ten minutes; the tubercle bacillus is not decolorised. In *pus*, the search is much facilitated by the use of "anti-formin," and this is a useful adjunct in the examination of fæces also. A patient suspected of tuberculosis of the bowel often suffers from diarrhœa; when this is the case, Emery's suggestion of giving sufficient opium to cause a solid stool is useful. The superficial parts of the motion are most likely to yield the bacillus, and are dealt with accordingly.

Puncture-fluids very frequently give negative results to ordinary microscopic examination, on account of the scantiness of the bacilli in them. However, the clot (if such occur), or the centrifugalised deposit, should always be searched thoroughly, as the demonstration of even a few bacilli of undoubted morphological characters is decisive. Cerebro-spinal fluid should be incubated, without shaking, for 24 hours, and the "spider-web" clot stained for bacilli. Failing this demonstration, the fluid must be used for inoculation purposes, a guinea-pig receiving a liberal amount (not less than 10 c.c. if possible). The inoculation method of diagnosis is, of course, available for the above materials also, as a final test.

The demonstration of tubercle bacilli in the *blood* has received attention of late years, but with widely different results in different hands. Reputable authorities state that bacilli can be seen in stained films in a very high percentage of all cases of tuberculosis, wherever the lesion may be. Others fail to confirm these results.

Indirect Methods of Diagnosis.—These depend upon the presence in the tissues of certain sensitising and immunising substances. They are indicated in doubtful cases of tuberculosis in which no material is available for investigation by direct methods (see above). The relative values of these methods are still under assessment; at present their values are probably in the order of their description here.

1. The Tuberculin Test.—The test depends upon the fact that infection by the tubercle bacillus renders the tissues supersensitive to the toxins of the bacillus, if these be introduced into it artificially. This supersensitiveness is shown by the production of certain "reactions" which are recognisable and are regarded as more or less "specific" in their nature. The test is performed in three ways.

(*a*) *The subcutaneous test.*—The use of "old tuberculin" by this route (Koch's test) is not without danger, and has been superseded in human practice by other methods.

(*b*) *The skin test* (Pirquet's test).—This is best employed quantitatively. Three or more strengths (*e.g.* 25, 50 and 100 per cent.) of a solution of old tuberculin are rubbed lightly into the skin of the arm, which has been

previously scarified. The appearance of papules and erythema at the site of vaccination constitutes a positive reaction.

(*c*) *The eye test* (Calmette's test).—This test is now seldom used.

(*d*) *The intradermal test* (Mantoux).—0·1 c.c. of 1 in 1000 and of 1 in 10,000 old tuberculin are injected into the cutis. Redness and œdema, appearing within a few fours and reaching a maximum on the following day, constitute a positive reaction. The test is an extremely delicate one and this fact restricts its clinical value.

(*e*) The erythrocyte-sedimentation rate is increased in all cases of active tuberculosis, but not only in this disease.

2. The Complement-Fixation Test.—This test is analogous to the Wassermann test for syphilis. It is claimed by some workers that it is positive in over 90 per cent. of cases of tuberculosis. The difficulty seems to be that it cannot be relied upon to distinguish an active lesion from one that is not active. Seeing that old and caseous tuberculous lesions exist in such a large proportion of all persons likely to be tested, and that these old lesions still suffice to give the complement-fixation test, its value is quite doubtful unless undertaken in a quantitative manner.

3. The Tuberculo-Opsonic Index.—This is now only of historical interest.

4. Cytological Evidence of Tuberculosis. — Another, and very useful, evidence of tuberculous infection is to be obtained in cases of pleural, peritoneal and meningeal exudates, by estimating the relative numbers of polymorphonuclear cells and of lymphocytes. It is found that, in pure tuberculous infections, the cell exudate is largely, and often almost entirely, lymphocytic in character. In pyogenic infections it is very largely polymorphonuclear; in mixed infections (tubercle with pyogenic infection) the cell-exudate is also of a mixed character (Widal and Ravaut).

Treatment.—This is prophylactic and curative.

1. Prophylactic.—The widest possible view should be taken of the preventive measures which are necessary in order to stamp out the disease. If, as seems certain, the three dominant factors in the persistence of the disease are—(i) the inherited tissue-susceptibility; (ii) the bacillus; and (iii) bad hygienic and economic conditions of life, it is clear that the problem is not a simple one.

(i) Families having an inherited tendency to tuberculosis should recognise the fact earlier and more thoroughly than is usually the case. The upbringing of the children needs special care, and occupations should be chosen for them when they reach puberty which keep them in the open air. Climatic considerations are also of importance in the case of these families.

(ii) As already stated, the two great sources of the tubercle bacillus are the sputa from infected pulmonary cases and tuberculous milk. The former of these is both a public and a private concern—the latter is almost entirely public. Pasteurisation is an effective safeguard.

(iii) This resolves itself into a series of sociological questions.

2. Curative.—*Non-specific measures.*—These consist in efforts at improving the patient's nutrition so as to increase the tissue-resistance to the infection—ample fresh air, plenty of good food, bodily and mental rest and exercise undertaken in graduated fashion under expert supervision. De-

tails of all these measures are given in the article dealing with pulmonary tuberculosis (p. 1208).

Specific measures.—With two exceptions tubercular sera and vaccines are of historical interest only. These exceptions are (*a*) Koch's Tuberculin; (*b*) Bacille Calmette-Guérin (B.C.-G.).

(*a*) *Tuberculin.*—This is used most for urogenital tuberculosis. (Doses as in text.)

(*b*) *B.C.-G.* (*Bacille Calmette-Guérin*).—This is a "live" vaccine prepared from a strain of tubercle bacillus which has been so attenuated that it has lost much of its capacity for producing disease.

It has been widely used in France for prophylaxis. Three doses of living bacilli are given by mouth to infants during the first 10 days after birth, before natural infection has occurred.

About 100,000 infants in France, mainly those born of tuberculous parents, have been treated. It is too early to assess the results, but there is one great objection to the method, *i.e.* the possibility that the organism itself may be capable of regaining virulence in the human body.

Chemo-therapy.—A number of substances have been used from time to time. The most recent, and perhaps the most successful, is Sanocrysin. (See p. 1210.)

General Tuberculosis

Synonym.—Acute Miliary Tuberculosis.

Definition.—A disseminate form of tuberculosis, giving rise to a very severe and fatal disease analogous to the septicæmias in pyogenic infection.

There are three clinical forms of the disease, according as the symptoms are chiefly referable to the lungs (the *pulmonary form*), or to the brain (the *meningitic form*), or are those of a general infection without focal signs. This latter form is often termed the *typhoid form*. The pulmonary form is described in the section dealing with pulmonary tuberculosis. The meningitic form is described in the section on meningitis.

Symptoms.—The *general* or *typhoid form* resembles typhoid fever very closely. There is usually a period of vague ill-health—as there is in typhoid fever—preceding the more severe illness. When the latter develops there is headache, insomnia, a soft but frequent pulse, rapid respirations, a dry tongue, slight cyanotic flush and pyrexia, which is usually less continued in character than in typhoid fever. Not infrequently the temperature curve is that of a quotidian intermittent fever. In a few cases the rise of temperature takes place in the morning instead of in the evening, a feature not infrequently seen in other pyrexias of tuberculous origin, though not confined to these. Progressive loss of flesh takes place, and also anæmia, but this latter condition may only be found by blood examination, the dusky flush of the face often masking the blood state on mere clinical examination. Towards the end of the illness, suspicious signs of one or other of the more focal manifestations of the infection often arise: copious fine râles over the lungs, tumidity of the abdomen with palpable enlargement of the spleen and liver, or cerebral symptoms suggestive of meningitic involvement. In a suspected case the chest should be examined radiologically, since the suggestive "snow-storm" appearance may be present if general tuberculosis has existed for more than ten days or so.

Diagnosis.—As the term "typhoid form" suggests, the disease resembling general tuberculosis most closely is typhoid fever. During the first week, or even during the first two weeks, diagnosis may be very difficult. In favour of typhoid fever are the persistence of headache, the presence of epistaxis, relative infrequency of the pulse-rate, diarrhœa and early tumidity of the abdomen. In favour of tuberculosis are a frequent pulse-rate, early cyanosis and intermission in the temperature curve. There is leucopenia in both diseases. A positive blood culture occurs during the first week in most typhoid cases, and agglutination with the patient's serum may reasonably be expected after the end of the first week.

Course and Prognosis.—The disease is invariably fatal, and usually within a period of 6 weeks from the onset of fever and symptoms directly referable to the disseminate infection. A few cases last as long as the eighth week, and one of the writers (H.) has seen a well-authenticated case in which the patient lived until the middle of the tenth week.

Treatment.—This is entirely palliative, there being no specific measures at present known to check the progressive nature of the infection, or to avert its lethal issue.

CEREBRO-SPINAL FEVER

Synonyms.—The name here chosen seems least open to objection. "Cerebro-spinal meningitis" is the best alternative, but cerebro-spinal meningitis may be caused by other micro-organisms than the meningococcus, and meningitis may not be present at all, or may not constitute the chief lesion, in some cases of meningococcus infection. "Epidemic cerebro-spinal meningitis" is much less desirable, because it suggests that there is an essential difference between the epidemic and the sporadic cases of meningococcus infection, which difference does not in fact exist. "Meningococcus infection" brings the various pathogenic possibilities of the micro-organism into line with those of the pneumococcus, with which it has close analogies, but the term does not connote a disease.

Definition.—A specific disease, due to infection of the body by the meningococcus, occurring both in epidemic and in sporadic form, and most often manifesting itself as an acute meningitis tending to involve the whole cerebro-spinal axis.

Epidemics of cerebro-spinal fever are marked by several features peculiar to the disease, offering a striking contrast with other epidemic diseases. For a long time these features were very difficult of explanation, until the existence of "carriers" became recognised, and supplied the solution to much of the epidemiological problem. Amongst these curious features may be mentioned the erratic nature of the outbreaks, the inability to trace the connection between one epidemic and another, the relative or even total escape of certain localities close to others in which the disease was rife, and the small proportion of persons affected in any one district. In closed communities, such as camps, and especially in times of war, the disease finds a fertile soil. When the "carrier rate" rises above 20 per cent. an epidemic is likely to ensue.

On clinical, bacteriological and epidemiological grounds there is no distinction to be drawn between sporadic and epidemic cases of cerebro-

spinal fever. But it is not entirely by means of the sporadic cases that the infecting agent persists, but by " carriers " also. There is little doubt, however, that from the sporadic cases, as from a smouldering infection, new epidemics light up. The present conception of the disease, from an epidemiological point of view, is that of a very widespread infection, with a total morbidity that is very low, but with foci of more intense virulence here and there. These foci of more intense virulence appear and disappear, being preceded and followed by a somewhat higher level of permanent incidence in the districts concerned.

Ætiology.—The geographical distribution of the disease is very wide—world-wide, in fact. A certain affinity is shown for the north temperate zone.

Epidemic cerebro-spinal meningitis is a disease of winter and spring. This seasonal incidence is borne out by all observers, and is a very important feature of the disease. It compares markedly with the seasonal incidence of poliomyelitis epidemics, which are at their height in the summer months.

The question whether cerebro-spinal fever is contagious or not has been a matter of much dispute. The facts would appear to indicate that the disease is contagious, but that the degree to which it is so is very slight. The proofs of the contagiousness of the disease are, briefly, these—(1) the occasional transmission of the disease to doctors and nurses ; (2) the occurrence of a succession of cases in one family and in the same house ; (3) the importation of the disease into a new country or locality ; (4) the mode of spread in any locality ; (5) the immunity enjoyed by collections of persons living under the same conditions as those affected by the disease, but unable for some reason to come into contact with them (Netter and Debré). Although direct contagion is uncommon, plenty of authentic instances of its occurrence have been reported.

THE MENINGOCOCCUS.—The meningococcus (*Diplococcus meningitidis intracellularis* of Weichselbaum) is rather smaller than the *M. catarrhalis* and larger than the gonococcus—the other two pathogenic diplococci which are Gram-negative in staining reaction. It is a strict aerobe, and requires the addition of some animal protein or of legumin to ordinary culture media to ensure growth. After cultivation for three or four generations it will grow on ordinary agar, but sub-cultures die rather suddenly. Optimum growth takes place at 36° to 37° C., and growth ceases at 42° C. and at 25° C. Vitality is low, especially to drying ; sunlight kills in less than 12 hours.

Types of the Meningococcus.—By employing the agglutination test, controlled by the absorption test, M. H. Gordon has differentiated four separate types of meningococci occurring in the cerebro-spinal fluid of actual cases.

IMMUNE SERA.—These were proved by Jochmann and by Flexner to possess potent immune substances when prepared from the horse by the usual technique. Standardisation is still, as in the case of nearly all bactericidal sera, almost impracticable. The great advance of past years has been the preparation of type-sera, following Gordon's researches. By the use of these the results of serum treatment, previously somewhat disappointing in this country, proved to be more successful.

The primary habit of the meningococcus, both in actual cases of the disease and in " carriers," is the upper part of the naso-pharynx and the posterior nares.

Symptoms and Course.—Cerebro-spinal fever is protean in its features and especially in its modes of onset. Out of the large number of different manifestations that occur, certain cases repeat themselves with sufficient constancy to constitute clinical "types," capable of description and of recognition.

1. The Ordinary or Acute Type.—The incubation period is difficult to estimate with accuracy; there are reasons for considering it to be 4 or 5 days. The illness begins with the usual symptoms of an acute specific fever, and for the first day or two, or for longer than this if the possibility of the disease under consideration is not borne in mind so as to lead to a special examination, there may be nothing to distinguish the illness from one or other of several acute febrile infections.

The onset is usually sudden, with fever, headache, general malaise and vomiting. The temperature usually rises rapidly and attains a fairly high degree on the first day (102° to 104°).

The headache is usually very intense, is often referred to the occiput, and shows little or no response to the customary palliative drugs given to relieve it.

There is frequently a rigor in the adult, or a convulsion in the infant or child. Vomiting is more often met with in children than in infants, and is quite common in young adults.

In addition to the three cardinal symptoms at the onset—headache, fever and vomiting—the following are quite common, but are not nearly so constant: delirium, pains in the neck and limbs, and some degree of catarrh either of the nose, naso-pharynx, conjunctiva, or ear. In some cases there is considerable bronchial catarrh and in others definite enteritis. In addition to the pains referred to the limbs there may be pain and swelling of the joints.

After some 2 to 4 days of these initial symptoms evidence of meningeal irritation begins to show itself in more or fewer of the following developments. The vomiting is repeated, despite the fact that the invasion symptoms are past. The pulse is irregular in rhythm, and in older children and in adults it is often relatively infrequent when compared with the height of the temperature. The respirations are irregular. The vasomotor system is unstable, leading to periodic flushing of the face and to the presence of *tâches cérébrales*. The patient lies on his side with legs drawn up and prefers the shelter of the bed-clothes. The pupils are dilated and the light reflex is sluggish. There is photophobia, with intolerance of noise and of all kinds of interference. Examination of the neck reveals a stiffness of the muscles, which cannot be overcome without pain. The hamstrings are found to be taut, so that the knees cannot readily be extended if the hips are flexed (Kernig's sign). The abdomen is retracted and the superficial reflexes are abolished. The mental state is one of restlessness and mild delirium with troublesome insomnia. The headache may become quite intolerable and may require morphine for its reduction. In a considerable number of cases a rash appears during the first week—either a number of large rose spots about the trunk and limbs, or a macular eruption like that of measles or a few small petechiæ scattered over the trunk, neck and extremities. Herpes is common, and is generally situated at the usual places—the angle of the mouth, the chin and the nose. There is a leucocytosis of considerable degree (20,000 to 40,000).

Towards the end of the first week the mental state changes to a condition which may perhaps best be described as one of resistant stupor: the patient can be roused by an effort at examination, or by a change of position; but either proceeding is resented, and he quickly resumes his huddled posture. The headache is less constantly severe, but shows sudden and marked exacerbations, often nocturnal, with complete insomnia. The neck rigidity increases, and the head is retracted. The back also becomes stiff. Flesh is lost rapidly. Polyuria is common, with polydipsia. The temperature generally remains fairly high, and, although this is by no means invariable, the fever approximates to the continued type.

Assuming that the course of the disease is not interrupted by lumbar puncture or by specific therapy, the condition of the patient remains much the same during the second, and perhaps during the third, week of the illness. But the wasting continues. The temperature often becomes intermittent in type. One of the three modes of termination will be followed.

(*a*) *Recovery.*—This is gradual when it occurs, and is often interrupted by sudden recrudescences, throwing the patient back into a state which leads to renewed anxiety. The temperature chart is often interrupted in its defervescence by sudden rises, with or without a corresponding recrudescence of the meningitic symptoms. Ultimately the fever completely subsides, the patient ceases losing flesh, the headache and stupor pass off, and the rigidities slowly disappear. The pulse-rate remains high for some time in a good number of cases, and some authors regard this as a sign that the patient is not yet free from the possibility of relapse, and therefore as an indication for caution in treatment. The actual stage of convalescence, once it is established, is rarely interrupted. If the temperature and pulse-rate have remained normal for fourteen days, the risk of relapse may be considered to be passed. It may be some weeks, however, before the patient is free from stiffness.

(*b*) *Death.*—The ordinary type of the disease is not often fatal during the first 2 weeks. When it is, the stupor passes into true coma, the pulse and respiration rise in frequency, and the temperature often shows a sudden ante-mortem rise.

(*c*) *Becoming chronic.*—More often, if the ordinary type terminates fatally, it is by passing into a subacute or chronic stage. If the "crises" already referred to continue, or if, despite the fall of temperature, there is no corresponding improvement in the general condition, a state of progressive emaciation supervenes, with a tendency to chronic hydrocephalus. The wasting is sometimes extreme, so that bedsores are unavoidable. The rigidity becomes marked, and approaches, even in adults, that degree termed cervical opisthotonos in infants. Feeding becomes difficult, and this adds to the wasting due to trophic disturbances. The sphincters usually relax, leading to incontinence. Papillœdema develops. The patient may continue in this unsatisfactory state for several weeks, or even months, and yet may eventually recover, and without any residual defects. More often, however, he gradually succumbs to the disease, or, if he eventually survives its ravages, it is to be left with mental defect, deafness, blindness, hemiplegia, or diplegia.

Opinions differ as to the frequency of true relapses in cerebro-spinal fever. This is probably due to the fact that what some authorities term relapses

others consider to be merely recrudescences. It is certain that the latter are very common; indeed, they are a characteristic feature of the disease.

2. The Superacute Type.—This form of the disease is common at the height of an epidemic. The invasion symptoms are abrupt, and the patient is from the first very ill. Delirium is marked, with most tiresome insomnia, and the headache may drive the patient to a state of acute mania. The temperature is usually very high (104° to 106°), and intermits. Skin eruptions are more constantly present than in the ordinary type; but are by no means necessarily petechial in character. Discharges are apt to occur from the nose and conjunctival sac. The tongue is dry and tremulous. The meningococcus can generally be grown from the blood by culture, and has even been demonstrated in cover-slip preparations made from the blood direct. The leucocytosis is high (30,000 to 40,000). After 3 or 4 days the active mental state changes to stupor; if the cerebral pressure is not now relieved by lumbar puncture this stupor passes into coma. Even if the pressure is relieved by this procedure there is a great tendency for the patient to slip back into a comatose state; then, with pulse, respirations and temperature all rising, with insensitive pupils and absence of corneal reflex, the surface of the body becomes livid, the lungs congested, and death occurs.

3. The Fulminating or Malignant Type.—This form is prone to occur during the evolution of an epidemic. But it is by no means rare as a sporadic manifestation of the disease. It is more often seen in older children, adolescents, and adults than in infants and younger children. The abrupt appearance of fever, headache and active delirium, rapidly passing into coma, and the whole course of the disease may not exceed 12 hours.

In all fulminating cases of cerebro-spinal fever there is a rapid development of septicæmia. In some of them the septicæmia covers the whole of the disease, symptoms of meningitis being absent, and the meninges being free from gross lesions on examination post mortem. Even more constantly than in the superacute type is a blood culture positive: but the course of the disease is too rapid to admit of a diagnosis by this method during life.

4. Mild Types.—These cases are said to be common during the decline of an epidemic. It is at present quite impossible to say with what frequency they occur, because it is certain that many of them are overlooked. They are often treated as cases of "influenza," owing to the resemblance they bear to that disease. Many cases of acute fever with headache and pains in the back and limbs are regarded as "influenza" from a diagnosis by exclusion. They are not subjected to a lumbar puncture because the condition does not seem sufficiently grave. And if they recover from an illness of a few days' duration this is thought to be confirmatory of the diagnosis. In the presence of an epidemic of cerebro-spinal fever, however, a very close scrutiny of these cases should be made, and if there is even doubtful neck-rigidity or Kernig's sign, the cerebro-spinal fluid should be examined. Even when lumbar puncture is not at first decided upon a swab from the naso-pharynx should be investigated for the meningococcus.

During an epidemic a patient who presents the symptom-complex of headache, malaise, pains in the back and limbs, slight fever, and some stiffness of the neck is probably suffering from a mild grade of meningococcus infection, and should be treated as such, by a lumbar puncture and the administra-

tion of sulphonamide. Subsequent measures will be determined by (*a*) the course of the disease; (*b*) the result of the examination of the cerebro-spinal fluid; and (*c*) the result of the examination of the naso-pharyngeal swab. The value of these cautionary measures is sometimes made apparent by the patient becoming rather suddenly worse after a few days, when it may be quite obvious that the nature of the disease is what was originally suspected.

5. Post-basic Meningitis of Infants (Cervical Opisthotonos of Infants).—These cases were first described (1878) by Gee and Barlow. These observers recognised that they were dealing with a specific disease which had no causative association with tuberculosis, syphilis, or rickets. At the time of these authors' observations no epidemic of this type of meningitis had been described, and the cases were thought, even by later writers, to be met with in sporadic fashion only. It has, however, been recognised that this clinical manifestation of meningococcus infection may occur in epidemics. The post-basic type has been less frequent in this country in recent years.

The characters of the micro-organisms present in these cases were originally thought by some workers to differ from those of the micro-organisms found in the acuter cases occurring in epidemics. This distinction has disappeared of late, and there is more or less consensus of opinion that, although the strain may vary, the causative diplococcus is essentially the same in the acute as in the chronic, and in the epidemic as in the sporadic cases.

Seeing that the clinical features, again, do not differ materially in this type of meningitis from those often seen in cases occurring in older children, and occasionally even in adults, nor from those often seen in infants at times of an epidemic, it follows from these considerations that the inclusion of cases of post-basic meningitis in a general account of cerebro-spinal fever is amply justified.

Post-basic meningitis occurs chiefly in infants between the ages of 6 months and 2½ years. The same type of the disease may, however, be seen in children up to the age of 4 or 5 years. The onset is usually sudden, with a convulsion in many cases, and very frequently vomiting. The temperature rises abruptly, but does not, as a rule, remain high. In most cases the fever has become slight, or is absent, by the end of the first week of the illness. A large number of the patients suffering from the disease are therefore without fever when they come under observation.

The main and characteristic sign of the disease, the retraction of the head, becomes marked about the third or fourth day. It usually persists, with increasing severity, throughout the whole course of the disease. With it the back becomes arched, so that in extreme instances the occiput and the sacrum may meet. The extremities are usually in a condition resembling tetany, the stiffness being persistent rather than paroxysmal. Progressive wasting is another constant feature, and the degree of emaciation is often very considerable and very rapid. Of the other symptoms vomiting is one of the most common, and may be very troublesome. The pulse and respirations are usually frequent, and may be irregular.

The disease in most cases quickly enters upon a chronic course. The infant lies motionless in its characteristic attitude for hours at a time, but is not usually comatose. Feeding is not as a rule difficult. The pupils are fully dilated. Blindness is present sooner or later in 30 per cent. of the cases

(Langmead), the origin of the condition being central, since papillœdema of any magnitude is quite uncommon. Blindness is rare in the cerebro-spinal meningitis of older children and adults.

Lumbar puncture yields similar results to those found in the ordinary type of the disease; but, as the condition progresses, it is found that the meningococcus fails to appear in the fluid, and the polymorphonuclear cell-content changes to lymphocytosis, indicating the chronic stage of the infection. Dry punctures are not uncommon, indicating the probable closure of the foramen of Magendie by the plastic exudate at the region of the bulb and fourth ventricle. Fluid removed from the ventricles during life, or the examination of fluid found in the ventricles post mortem at this stage, often reveals the meningococcus, showing that the disease is still, in its chronic phase, to be regarded as a persisting infection. Indeed, *the post-basic meningitis of infants is probably to be considered as a meningococcus infection of the pia-arachnoid system with a special tendency to involve the cerebral ventricles by ependymitis.* The peculiar symptoms and course of the disease are thus explained.

Owing to the early development of hydrocephalus in this type of the disease, and the elastic nature of the infant's skull, the head enlarges in all directions, with bulging of the fontanelles and opening of the sutures between the bones. The shape of the skull thus approximates to that of congenital hydrocephalus. The eyes are turned downwards, and the sclerotics above the cornea are exposed by retraction of the upper lid. If this condition of acquired hydrocephalus has lasted for some weeks, there may be enlargement of the superficial veins about the nose and orbits, and running over the temporal regions to the vertex.

The mortality in this type of the disease is very high, probably over 80 per cent. Some of the cases linger for many weeks, and a few very gradually recover, with, all too often, residual blindness and also perhaps deafness. But the majority succumb to the intracranial pressure effects produced by the distended ventricles, in from 4 to 6 weeks from the onset of the disease.

Complications.—1. *Hydrocephalus* may arise soon after the onset of the disease, or it may develop, and often rather suddenly, during its course, or it may be the final anatomical expression of the infective process, the counterpart of the symptom-complex seen in the chronic state of the disease. Certain symptoms are specially suggestive of the condition: pallor, cyanosis, increased frequency of the pulse with diminution in its tension and volume, shallow respirations, and stupor or coma supervening rather suddenly upon a previous state of consciousness.

If hydrocephalus arise at a later period of the disease than the end of the first week it may show itself with surprising suddenness, and sometimes in patients who seem to have been improving satisfactorily. In addition, to the symptoms just enumerated, there is a recrudescence of the headache, vomiting and fever, which may have to a large extent subsided. More often it appears gradually and concomitantly with the progressive cachexia of the chronic type of infection. A valuable sign of its presence in children and adults is the presence of a resonant note to percussion over the anterior horn of the lateral ventricle (Macewen). This sign is best obtained by placing the head in an upright position and inclining it to one side. The sign is not present in infants in whom the fontanelles are still open.

Hydrocephalus of the chronic stage of the disease is seen very constantly in infants suffering from the post-basic type of infection. Emaciation is a constant feature. The child lies for hours without stirring. There may be reiterated automatic acts, such as the biting of nails or the loosening and pulling out of teeth. The patients are rarely comatose. Vomiting and convulsions may occur.

2. *Psychic Disturbances.*—These are not very common, if the delirium and stupor are excluded. But the delirium may develop into mania, urged thereto by the violence of the headache. During convalescence it is not very uncommon to observe temperamental changes, such as puerility or emotionalism, which rarely persist for very long. Secondary dementia is, however, not unknown.

3. *Motor Defects.*—Cranial nerve palsies are very uncommon. There are three groups of paralytic complications, but none of them is common.

(*a*) *Hemiplegia* and, less often, *monoplegia* of cortical type. This usually appears at the height of the disease, and is generally of temporary duration.

(*b*) *Flaccid paralysis* localised to one extremity or to a part of one extremity. The tendon-jerks are lost. Muscular atrophy may ensue, and R.D. may develop. The prognosis for the limb is by no means bad, and complete, or almost complete, recovery is probable.

(*c*) *Spastic ataxia.*—It is not uncommon to find convalescent patients very unsteady on their legs when they first begin to walk. Little children often refuse to walk at all for a time, even if they had learnt to do so before the illness began. Older children sprawl about the floor. Adults tend to topple over in an indiscriminate manner. In the majority of these cases there are no signs of organic disease, and the return to a normal gait is usually only a matter of time. In a few of the cases, however, the ataxia is accompanied by exaggerated knee-jerks, true ankle-clonus and extensor plantar response: a state of spasticity. The sphincters are intact, and there is no anæsthesia or analgesia. According to Sophian, who drew attention to these cases, the pupils often remain dilated, with a sluggish light reflex. Recovery, though slow, is the rule.

4. *Special Senses.*—Complications involving the eye are very variable, and yet, in relation to the essentially nervous character if the main lesions of the disease, they are not very common. Fortunately, with the single exception of that form of blindness so often seen in the recovered cases of the post-basic type of the disease, very few if the eye complications are permanent. Inflammatory lesions include conjunctivitis, keratitis, iridocyclitis and (rarely) cellulitis of the orbit. Nervous lesions include extrinsic ocular defects which are not uncommon, but are generally transitory (*i.e.* spasmodic). Amaurosis is relatively common in the post-basic infection of infants; it is fortunately unusual in the more acute infection of children and adults. It is in most cases unaccompanied by any changes in the optic disc, and is therefore to be attributed to cortical changes associated with hydrocephalus. In some cases, however, a state of secondary optic atrophy is present. Optic neuritis is not a common complication; but papillitis, or a lesser degree of change even than this, is said by French authors to be extremely common.

The chief complication affecting the ear is meningitic deafness. This is a common and very serious complication, serious because when it occurs it is

apt to be permanent. The auditory defect generally begins early in the course of the disease, and usually before the end of the first week. It is usually bilateral, which adds to the seriousness of the trouble in the event of its becoming permanent.

5. *Arthropathies.*—A certain degree of painful stiffness, and even swelling of the joints, is not at all uncommon as a transitory symptom in cerebro-spinal fever. Occasionally, however, one joint shows evidence of much more intense infection, becoming red, swollen and very painful with the slightest movement. It may suppurate, and secondary infection may occur.

6. *Other complications* are the broncho-pneumonia already referred to in little children; occasionally pneumonia in adults; and enteritis.

Lumbar Puncture.—In any suspected case of meningitis a lumbar puncture is as clearly indicated as is puncture of the chest in a suspected case of pleuritic effusion, or a blood-count in a suspected case of leukæmia.

The Cerebro-spinal Fluid in Meningococcus Meningitis.—1. *Pressure and the amount.*—The pressure is generally more than 200 mm. of cerebro-spinal fluid as measured by a manometer fitted to the lumbar puncture needle. The amount of fluid which flows away before the normal pressure is re-established depends upon the pressure and the consistency of the fluid; it averages about 30 c.c.

2. *Naked-eye appearance.*—Various grades of turbidity are met with, from very slight opalescence to a highly purulent exudate. The degree of turbidity varies with the stage of the disease at which the lumbar puncture is undertaken. In the invasion stage the fluid may be almost clear; in the acute meningitic stage the fluid shows marked turbidity; later, again, as the inflammatory phase passes, the fluid becomes clearer. The presence of blood probably always means that a vessel has been punctured by the needle. Some degree of clotting takes place when the fluid is allowed to stand, flakes of fibrin appearing at the bottom of the tube.

3. *Chemistry.*—The protein is increased in amount: instead of the faint opalescence which appears on boiling the normal fluid, a definite coagulum is produced, and an opaque ring appears when the fluid is poured gently on to the surface of strong cold nitric acid. A quantitative estimation of the protein shows that it may be present to the extent of 0·2 to 0·3 per cent. The globulin moiety of the protein is also increased. Sugar is greatly diminished and often absent. The chloride content also is lowered as in other forms of meningitis: it is seldom less than 700 mg. per cent., whereas in tuberculous meningitis a reading below 680 is the rule.

4. *Cytology.*—In the early or invasion stage of the disease there is a quantitative increase in the lymphocytic content, a fact which often escapes observation if the lumbar puncture be delayed. With the arrival of the acute meningitic inflammation the chief cell present is the polymorphonuclear, usually in large numbers. At the stage, therefore, at which most lumbar punctures are undertaken, the cell content is chiefly polymorphous (70 per cent. to 80 per cent.). Later, when the stage of chronic hydrocephalus ensues, the lymphocyte again becomes the dominant cell, and in much greater numbers than in healthy fluid. Most observers, however, describe cases of undoubted meningococcus meningitis in which the cell content is chiefly lymphocytic throughout. In the post-basic type of the disease the cells are most often lymphocytes for the greater part, and the same may be said

of cases which are in a chronic stage whilst under investigation, whether the chief seat of the effusion be at the root of the bulb or elsewhere.

5. *Bacteriology.*—Films made direct from the cerebro-spinal fluid, or, better still, from the centrifugalised deposit, show intra- and extracellular meningococci in the great majority of cases at some time or other in their course. If a careful search be made and no cocci are discovered, it must not be assumed that none are present until the device of incubating the fluid as a whole before it has been allowed to cool is undertaken, and until cultures made upon suitable media are found to be sterile. The number of cocci seen, and their disposition with regard to the cells of the exudate, are matters of great variability. These things depend in the main upon (*a*) the stage of the disease, (*b*) the intensity of the infection and (*c*) the influence of treatment.

Diagnosis.—*The chief difficulty lies in not suspecting the presence of the disease.* It is, of course, much more easy to bear in mind the possibility of cerebro-spinal fever during the presence of an epidemic than at other times. Cases which go undiagnosed, at least during the first part of their course, are those sporadic cases which generally happen to be atypical.

The reason why it may not be possible to decide on clinical grounds whether meningitis is present or not is because several infective processes, other than that due to the meningococcus, are apt to produce symptoms highly suggestive of meningeal irritation. This state of meningeal irritation, when due to toxæmia and not due to actual meningitis, has been termed *meningism* or *meningismus*. The question whether such a state is entirely toxic, or whether it is due to definite though slight changes in the meningeal tissues which just stop short of an inflammatory exudate, is problematical.

The diagnosis of cerebro-spinal fever may be conveniently considered under three heads—(1) from various acute infective processes with toxæmia, leading to "cerebral" symptoms; (2) from certain acute cerebral diseases of primary origin; (3) from other forms of meningitis.

1. The Diagnosis of Meningitis from Toxæmia merely.—The question is settled partly by the clinical data and partly by an examination of the cerebro-spinal fluid. In a case of fever with "head symptoms," the following differential points should be borne in mind:

(1) *If headache and delirium synchronise, meningitis is probably present, and not merely toxæmia.*—Contrast an ordinary case of typhoid fever (toxæmia), in which headache and delirium alternate, the patient being free from pain when he is delirious, with cerebro-spinal fever (meningitis), in which the patient's headache and delirium are both present at the same moment.

(2) *Vomiting.*—If this occurs not merely at the onset of the fever, but on subsequent days also, at a time when the invasion period of the infection may be said to be passed, it is evidence of meningitis.

(3) *Pulse and respirations.*—Irregularities in rhythm are in favour of meningitis, and so is a relatively low pulse-rate in comparison with the height of the temperature, provided typhoid fever can be eliminated.

(4) *Papillœdema*, though its presence is much in favour of meningitis as against toxæmia merely, is not of much value in this connection, because it is usually absent at the early stage of the disease when the diagnostic problem requires urgent solution.

bacillus is isolated from the lumbar puncture fluid, with the exudate of an acute meningitis, and definite symptoms, are not usually cases in which influenza has been suspected, still less diagnosed. Such cases are preferably termed "Pfeiffer bacillus meningitis."

(4) *Typhoid meningitis.*—A true infection of the meninges may occur in typhoid fever, but it must not be inferred that a patient necessarily has typhoid meningitis because the bacillus is grown from the lumbar puncture fluid. This may occur without clinical evidence of meningitis and without histological and chemical changes in the cerebro-spinal fluid characteristic of meningeal inflammation.

(5) *Tuberculous meningitis.*—This is by far the commonest form of acute meningitis and therefore deserves fuller mention. The most helpful points in a differential diagnosis from meningococcus meningitis are the following. Tuberculous meningitis is rarely so sudden in its onset, the meningitis symptoms being preceded by a longer period of malaise, which begins less abruptly than the invasion symptoms of cerebro-spinal fever. The temperature is seldom high, except as an ante-mortem event, the usual range being 99° to 101°. Retraction of the head is transient and ill-marked, or is absent. Photophobia is more common than it is in cerebro-spinal fever. In adults aphasia is often a common and an early symptom. True (paralytic) squint is common. The "peevish" condition in children is much more marked during the first week. In both children and adults the depth of the stupor after about the tenth day is much greater. The discovery of tubercles in the choroid is pathognomonic, but these lesions rarely appear before the third week of the disease, and are therefore not of much service for diagnosis. Some authors lay stress upon the presence of signs of tuberculous disease elsewhere in the body as assisting in the diagnosis, but this is, of course, not true. Except in the case of adults, and by no means always then, there are rarely any such signs. The leucocyte count affords no differential help as from cerebro-spinal fever, a leucocytosis of considerable size (15,000 to 30,000) being present in tuberculous meningitis. The abdominal reflexes are usually retained, whereas in meningococcal meningitis they are prone to be lost early.

However high a degree of probability that a patient is suffering from meningitis may result from a general examination, confirmation of this view rests entirely upon the results of lumbar puncture. For three reasons it should not be deferred: it establishes the diagnosis that meningitis is present; it decides the nature of the infection; it is a valuable aid to treatment in the event of a positive result.

Prognosis.—The mortality in cerebro-spinal fever is undoubtedly higher in the epidemic than in the sporadic cases, if the post-basic meningitis of infants, in which the mortality is very high, be excluded. There are, however, no good figures upon which to base an estimate of mortality in the sporadic cases. In epidemics the mortality prior to the introduction of serum treatment was about 70 to 80 per cent. After its introduction the mortality fell to half this figure. With sulphonamide treatment the figure has probably reached 10 per cent.

The influence of age is noteworthy. The disease is extraordinarily fatal in infants (patients under 2 years of age). This statement holds good both for the post-basic cases which are so often subacute or chronic in character, and

for the acute cases. The mortality is lowest between the ages of 5 and 10 years.

A fulminating form of onset is invariably bad, and the mortality in these cases is very high, if indeed it is not 100 per cent. In the cases with less vicious invasion symptoms, one or more of the following symptoms betoken a grave issue: early loss of consciousness, wild delirium, persistent insomnia, extensive hæmorrhagic eruption, cyanosis. Later in the course of the disease the worst sign is the appearance of hydrocephalus.

The degree of fever, the intensity of the headache, the amount of rigidity, the presence of marked emaciation, frequency and irregularity of the pulse, rhythmical respirations, the presence of herpes—none of these things yields any information of value in predicting the issue of the disease. *In few other diseases, if in any, is it possible for the patient to be so ill and yet to recover completely, as in cerebro-spinal fever.*

The most important fact bearing upon prognosis is the stage in the disease at which treatment is begun.

Treatment.—1. PROPHYLACTIC.—The principles governing prophylaxis are those applicable to infectious diseases in general. Although it would appear that the healthy carrier is more responsible for the spread of the disease than the patient himself, it is none the less important to isolate every case of the disease and to exercise all precautions against further contact with healthy persons. Whenever possible the patient should be transferred to a hospital, and preferably to an institution where the staff is accustomed to deal with infectious diseases.

All contacts who are found to be carriers should be placed under quarantine, and should be kept there until the naso-pharynx is free from meningococci. The carrier should live as far as possible in the open air. For lavage of the naso-pharynx, and for a gargle, a weak solution of izal may be used, or peroxide of hydrogen, or a 1 : 1000 solution of permanganate of potash, adding 1·5 per cent. of sodium sulphate to assist penetration (Gordon). For spraying the nose or fauces, a 1 per cent. solution of iodine with 2 per cent. of menthol in parolein may be used.

The use of a meningococcus vaccine for the purpose of clearing the throat has not proved to be successful.

2. CURATIVE.—(1) *Drug treatment.*—The introduction of sulphanilamide has revolutionised the treatment of this disease. It is of vital importance that the drug should be given at the earliest possible moment after the diagnosis has been made or is strongly suspected. In the majority of cases adequate doses are well tolerated and, whenever possible, the drug should be administered by the oral route; if the patient is too ill to swallow, it is given by a stomach tube. Only when vomiting is frequent is sulphanilamide to be administered by injection. For an adult the initial dose in the acute form is grm. 2, followed every two hours by grm. 1, so that a total of 12–13 grm. are given in the first 24 hours. During the second and third days grm. 1 should be administered every 2 hours by day and every 4 hours by night, that is, 10 doses in each 24 hours. If treatment on these lines has been started before the fourth day of the disease it is probable that the temperature will have fallen by the end of the third day of treatment. If so, the dose of the drug should be halved during the next 2 days, though the frequency of administration should be maintained.

The persistence of an ensuing temperature of 99°–100° does not necessarily imply that the infection is still active (see p. 39).

(2) *Serum treatment.*—The indications for the use of serum are (*a*) intense toxic symptoms, (*b*) unsatisfactory response to sulphonamides and (*c*) evidence of idiosyncrasy to these drugs (see p. 16). In (*a*) the serum is used as supplementary to sulphanilamide, not as a substitution for it. It is given intrathecally in doses of slightly less bulk than the amount of cerebro-spinal fluid removed. In highly toxic cases it may also be administered intravenously, in doses of 50–100 c.c. diluted to 250–500 c.c. with normal saline.

The serum may be allowed to flow by gravity into the *lumbar cisterna* following lumbar puncture, or it may be injected with a syringe which fits the lumbar puncture needle; the serum must be warmed to body heat and the injection made very slowly. The volume of serum injected must not exceed that of the cerebro-spinal fluid withdrawn. Serum may also be introduced into the *cisterna magna.* To reach this the needle must pass through the posterior atlanto-occipital ligament, which is not nearly so thick and resistant as are the interspinous ligaments between the spinous processes of the lumbar vertebræ, before entering through the foramen magnum. The posterior rim of the foramen magnum in the adult is just over 1 cm. from the posterior surface of the medulla oblongata, whereas a distance of only 0·5 cm. separates the lowest part of the medulla from the posterior arch of the atlas; the puncture therefore should be made as near to the upper border of the atlanto-occipital ligament as possible, and the needle inclined upwards. The patient lies on his left side, with the head erect; if head retraction be present, a general anæsthetic is essential in order that the requisite position may be assured. The uppermost bony point palpable in the mid-line of the back of the neck is the spine of the axis. The skin in this area is cleaned and, if general anæsthesia is not used, the tissues are infiltrated with sterile local anæsthetic. After this has had time to act, the skin is nicked with a sharp-pointed knife just above the level of the spine of the axis in the middle line. A fine lumbar puncture needle with a very short bevel is now inserted through the nick, and its direction so adjusted that it is continuous with a line passing through the level of the external auditory meatus to emerge on the forehead about 3 cm. above the bony prominence at the root of the nose, known as the glabella. The needle pushed steadily along this line will impinge on the occipital bone just posterior to the foramen magnum; the correct depth is thus determined and the needle withdrawn, almost to the skin, its direction altered slightly downwards and on reinsertion the point enters the cisterna just below the rim of the foramen; this is apparent to the operator by the sense of diminution in resistance to the passage of the needle. The cisterna magna is entered at a distance of 4·5 cms. from the skin in an adult of average build.

With regard to repetition of the serum, Flexner laid down an arbitrary rule for guidance on this matter, recommending the use of serum daily for 4 or 5 doses, and advising that after this the practitioner should be influenced by the subsequent clinical condition of the patient and by the state of the lumbar puncture fluid at successive operations. Some such custom as this remains the usual one in the ordinary type of the disease. It is desirable to vary this rule in individual cases.

If the case is of the superacute type, it is well to repeat the dose of serum in 8 to 12 hours and again after the same interval. In this way an effort is made, consistent with the precautions already referred to, to get as much serum as possible into the cerebro-spinal sac during the early stages of the disease. After these initial 3 doses an interval of 24 hours may be allowed to pass before the next dose is given.

No doubt the best indication for the repetition of the serum is the condition of the meningitic exudate as seen at successive punctures. The lumbar puncture fluid should always be examined by a competent observer whenever this is possible. The indication for further serum is proportionate to the number of meningococci still present. But it is not often practicable to prepare a stained film of the fluid straightway so as to be guided by the result. The decision whether to use serum or not must in most cases be determined by a consideration of the clinical condition together with the naked-eye characters of the fluid. In regard to the latter it may be said that if the fluid is still turbid (indicating the presence of polymorphous cells), it is well to give more serum.

(3) *General management.*—The diet is to be adjusted to the patient's condition. The disease is an exhausting one, and as full a dietary as is consistent with the state of the digestive secretions is to be allowed. If the fever is a conspicuous feature, and the patient is drowsy or delirious, the mouth is usually dry; the diet is then necessarily restricted to fluids, which should be given in the form of diluted milk, and freshly prepared meat essences, in small quantities at frequent intervals. Water should be given freely. If the patient is in a state of stupor the act of swallowing must not be relied upon; feeding must then be by the passage of a nasal tube three or four times in the 24 hours. According to the age of the patient, from 5 to 10 ounces of citrated milk and water (equal parts), or of peptonised milk, or of beef essence are allowed to run into the stomach from a funnel attached to the tube and held at the necessary height above the bed. If vomiting is troublesome, peptonised milk should only be used, or whey or albumin water. If this symptom is persistent, it may be advisable to put no food at all into the stomach for 24 to 48 hours, relying upon saline injections (5 to 20 ounces according to age) per rectum every 6 hours, supplementing these, if thought desirable, by the subcutaneous use of a 10 per cent. solution of dextrose in normal saline.

The bowels are usually constipated; it is therefore frequently necessary to use purgatives, avoiding salines if sulphonamide is being given. If the patient is comatose early in the disease, when treatment is beginning, it may be advisable to give 2 minims of croton oil in butter or moist sugar.

Urinary difficulties do not usually occur unless the patient is unconscious, in which case it is important to bear in mind the possibility of retention, which may lead to "overflow incontinence." This condition indicates the use of the catheter, with the customary care in the matter of asepsis.

(4) *The treatment of certain symptoms.*—Headache is usually the most distressing symptom calling for special treatment. Phenazone, caffeine, and acetylsalicylic acid may all be tried in full doses; morphine may be imperative in some cases, because nothing else may be of any service. Restlessness,

delirium and insomnia,—if these symptoms are troublesome a trial should be given to some such combination as the following:

R Ammon. bromid., grs. 10-30.
Tr. valerian. ammon., min. 10-30.
Syr. chloralis, min. 20-120.
Aquam ad fl. oz. 1.
S.—Secundis horis ad doses iv–vi.

The pains and the stiffness are best treated by warm baths at a temperature of 102° to 104° F.

If the delirium is exhausting or the condition verges upon mania, vapour of chloroform may be used, or morphine with atropine may be given. Hyoscine should be avoided.

In arthritis the affected joint is best treated by fixation, by the application of hot stupes, and by liquid. If the effusion becomes considerable, or does not quickly yield to these measures, the joint should be aspirated.

(5) *The repetition of the lumbar puncture.*—A lumbar puncture of necessity precedes the diagnosis. When sero-therapy is in force the puncture is, of necessity, repeated at each dose of serum. There remains the question of the therapeutic value of thecal drainage here as in the other forms of pyogenic meningitis undergoing sulphonamide treatment. There are reasons for thinking that drainage at certain intervals, especially in children, tends to prevent the development of the most serious of the complications of the disease, a state of hydrocephalus. The writers are of opinion that the process has beneficial effects upon the course of the disease in many cases. This, notwithstanding the fact that whole groups of cases have been successfully treated by chemotherapy with no further lumbar puncture than that made for diagnosis.

(6) *Treatment of hydrocephalus.*—If a condition of hydrocephalus has been diagnosed, it is advisable to tap the lateral ventricles and to inject serum. This procedure is not so difficult nor so dangerous as may be supposed.

(*a*) The patient is usually an infant with open fontanelles. The region of the anterior fontanelle is shaved and the skin is sterilised. A stout needle, to which a syringe can be attached, is inserted at the lateral angle of the fontanelle, and is gently pushed towards the mesial line for a distance of an inch or an inch and a half. In older patients a special drill may be necessary. The fluid is usually under considerable pressure, so that it becomes quickly known when the needle reaches it. It is not necessary or advisable to attempt to withdraw more fluid than comes into the syringe with very gentle aspiration. With great care, an amount of serum less in bulk than the fluid withdrawn is now introduced into the ventricle.

(*b*) In older children and adults the operation of decompression becomes necessary; and here again, though a much more serious procedure, the practitioner should not hesitate to give the patient the benefit of the operation and of the use of serum by this special route.

HORDER.
A. E. GOW.

TETANUS

Synonym.—Lockjaw.

Definitions.—An infective disease, due to the toxins of the tetanus bacillus, and showing itself by tonic spasm of the masseter and other muscles with paroxysmal exacerbations.

Ætiology.—The bacillus of tetanus is a slender rod 4 to 5 μ in length and from 0·3 to 0·8 μ broad. It is a spore-bearing anaerobe. The vegetative forms are slightly motile, and when stained by special methods show numerous fine flagella arranged all round the bacillus. In material from infected wounds, and usually in cultures after 24 hours' incubation at 37·5° C., spores occur. These are terminal, giving rise to the characteristic drumstick appearance. As cultures grow older the numerical proportion of spore-bearing forms increases, and in very old cultures only spore-bearing forms or spores are found.

Distribution.—In nature the tetanus bacillus is found in the soil of highly-manured districts, and in the dejecta of various animals, especially the herbivora, in the intestines of which it exists without causing pathogenic effects. By comparison with the widespread distribution of the bacillus and its spores the disease is rare. In infected wounds the bacillus occurs with other spore-bearing anaerobes associated with pyogenic cocci, and saprophytic organisms of various kinds. In consequence of its association, in nature and infected wounds, with other organisms, the bacillus is difficult of isolation, as a large proportion of the associated organisms grow with much greater rapidity. Use is made of the fact that the spores will resist a temperature of 80° C. for an hour. Suspected material is inoculated into agar or serum-agar slopes or deep tubes of glucose-agar, and incubated for 48 hours. The culture is then subjected to a temperature of 80° C. for three-quarters of an hour, and subcultures are made on agar plates which are incubated anaerobically. By this means all non-sporing bacteria, and the vegetative forms of the spore-bearers, are killed, and only spore-bearing organisms remain to be dealt with.

The disease follows *injury* to the tissues in most cases, and even when no injury is known to have occurred, it is highly probable that some slight abrasion has been present. The term "idiopathic tetanus" has been given to those cases in which no discoverable injury is present. Those wounds, usually of the hands, in which the tissues have been badly damaged rather than cleanly cut, are specially liable to be followed by tetanus infection. Cases have occurred from the use of contaminated gelatin used in subcutaneous injections, and from catgut sutures similarly infected.

Tetanus is more common in tropical than in temperate zones. A special form of the disease, *tetanus neonatorum*, is peculiar to the tropics, and results from sepsis in attending to the child's navel. This variety, which has occurred in epidemics, is "almost peculiar to infants of the filthy poor" (Hirsch, 1886).

Pathology.—In nature the disease is produced by the introduction of infected material through an abrasion or wound, which may be so minute as to escape detection. Probably there is no such thing as idiopathic tetanus, but infection is possible through the bronchial or even intestinal mucosa.

If the bacilli or spores, free from toxin or from pyogenic cocci, be intro-

duced into an animal, infection may fail to occur, the protection afforded being probably accounted for by phagocytosis, for if spores enclosed in a paper sac be introduced into a susceptible animal infection occurs, as the sac protects the spores from phagocytosis. The presence of pyogenic cocci, other micro-organisms, and the fragments of bone and foreign material incidental to compound fractures and gun-shot wounds, all conduce to the conditions favourable to growth of the tetanus bacillus.

The *period of incubation*, following infection with tetanus bacilli, varies with different animals. In man a period of from 2 to 14 days occurs, but the period may be longer, and as a rule a long incubation period means a more favourable prognosis.

Tetanus toxin.—The tetanus bacillus, like the diphtheria bacillus, produces its pathogenic effects by reason of the soluble toxin it elaborates. Bacterium-free filtrates of cultures, as shown by Kitasato, when injected subcutaneously or intravenously into mice, cause tetanic spasms, at first in the neighbouring muscles and later more generally, and death has resulted.

Tetanus toxin is one of the most powerful poisons known, the fatal dose of a probably impure toxalbumin for a mouse being found by Brieger to be 0·0005 mgm.

Different degrees of resistance to the toxin are shown by different animals. The horse and man are the most susceptible. On a basis of weight the horse is twelve times and the guinea-pig six times as susceptible as the mouse, while the hen is two hundred thousand times as resistant. The incubation period is shorter when toxin is intravenously injected than when introduced subcutaneously, and is shorter in smaller than in larger animals.

It has been proved that toxin is absorbed by the end-plates of motor nerves. This was shown by severing the sciatic nerve of an animal near the spinal cord. The corresponding hind limb was then injected with toxin. A portion of the divided nerve was then placed in another animal and tetanus resulted, while if the nerve were cut distally, and a proximal portion thereof were transplanted, no infection occurred, though in both cases the nerves were equally bathed in lymph containing toxin. And, again, if an excess of toxin be injected into a sound limb only that portion of a nerve distal to a section in another limb shows absorption of toxin. Introduction of a lethal dose of toxin into a nerve such as the infra-orbital, containing no motor filaments, is not followed by characteristic tetanus symptoms.

The toxin passes centripetally up the nerve and affects the motor nerve cells corresponding thereto, thus accounting for the longer incubation period in larger animals. If antitoxin be injected into a mixed nerve, such as the sciatic, toxin is prevented from passing up that nerve; but toxin injected into a similar nerve will act lethally even though a large excess of antitoxin had been previously injected intravenously. In one case, indeed, it was shown that a dose of toxin injected into the sciatic nerve of a highly immunised animal caused tetanus. Possibly these results are accounted for by the now well-known difficulty of bringing antibacterial and antitoxic bodies in the blood to bear on the cells of the central nervous system, a difficulty which has been met, to a certain extent, by the introduction of intrathecal medication.

Symptoms.—The incubation period has already been referred to. The

earliest symptom is, in the great majority of cases, the so-called *trismus* or tonic spasm of the masseter muscles. Beginning as a slight stiffness, this increases until the jaws are firmly clenched, the patient being unable to open the mouth. The stiffness may involve the muscles of the neck at the same time as the jaws, or a little later. The facial muscles are affected next, and the facies presents the *risus sardonicus* due to the tension in the frontalis and in the muscles at the angles of the mouth. The muscles of deglutition are another group early affected. There is, from these parts, a steady spread of the spasm to the trunk and then to the limbs. Rigidity tends to appear early in the rectus abdominis and in the adductors of the thighs. The tendon jerks are exaggerated and attempts to elicit them produce spasms, local or general. The tonic spasm in the muscles of the trunk usually show exacerbation in paroxysms, with resulting postures termed respectively opisthotonos, emprosthotonos and pleurothotonos, according as the muscles of the back, abdomen or one side of the body are in a state of spasm. These paroxysms may be induced by divers irritants, and are agonisingly painful. Retention of urine is common.

Less common manifestations include a local contracture of muscles in the neighbourhood of the wound, which may precede trismus or more general spasm by several days. Thus, in a wound of the forehead there may be a facial palsy or an ophthalmoplegia on the same side or, with a wound of the hand or foot, painful spasm of the muscles of the limb may develop before spasm appears elsewhere. In some of these local forms general spasms may be absent throughout or, if trismus is present, this may be transient. In "*local tetanus*" the incubation period is sometimes as long as 30 days.

The disease is often apyrexial, but in some cases the temperature rises with the development of the general symptoms, which include headache, pains in the back, anorexia, constipation, insomnia, yawning, sweating and a facies of great anxiety. Consciousness remains clear. The cerebrospinal fluid is unaffected.

Course.—The course of the disease is variable. Sometimes it is as short as 4 or 5 days, the patient dying of spasm of the glottis, asphyxiation, bronchopneumonia, heart failure or exhaustion. Other cases, less fulminant, last from 7 to 14 days. A few seem to deserve the term "chronic."

Diagnosis.—A relatively trivial disease which may, however, cause some anxiety from its resemblance to the trismus of tetanus, is the fixation of the jaw seen in certain cases of *septic throat* and *septic*, especially impacted, *teeth*, with phlegmonous involvement of the floor of the mouth, periosteum, etc. Careful examination of the mouth nearly always suffices to determine the real nature of these cases, and the presence of enlarged and tender cervical glands assists the diagnosis.

Strychnine poisoning presents features resembling tetanus in that the spasms are very similar in both diseases. But between the spasms in strychnine poisoning the muscles are relaxed, a condition never seen in tetanus. Another point of distinction is the fact that trismus and cervical rigidity never exist alone in strychnine poisoning, whereas they frequently do in tetanus.

In any doubtful case of injury, in which there are damaged tissues, bacteriological investigation of the exudate and of material from the depths of the wound should at once be made.

Prognosis.—This is always grave. The mortality in a large series of cases appears to be nearly 60 per cent. (Hill). Infants and children rarely recover. The absence of fever, a more or less normal pulse-rate, a long incubation period, and a slow development of the symptoms are favourable points. If the patient reaches the tenth day of the disease, his chance of recovery is considerably increased.

Treatment.—1. PROPHYLACTIC.—All wounds of a suspicious character should be well curetted under a general anæsthetic, the raw surface should be thoroughly treated with antiseptic and antitoxin administered.

Antitoxin has for some time been used in connection with wounds infected with road-sweepings, or garden soil, and in America chiefly in cases of wounds connected with Independence Day celebrations, in consequence of which injections a very definite fall in the death-rate resulted.

During the War of 1914–1918 antitoxin was used on an extensive scale. During the early period, with no special arrangements for prophylaxis, the incidence was about 8 per 1000. Later, with the use of 500, and then 1500, units of antitoxin, the incidence fell to 1 in 1000.

In 1924 it was shown that tetanus toxin might be so treated as to lose its toxicity and still retain its antigenic power. The material, called "toxoid," has been proved of great service as a preventive agent. At the R.A.M. College it has been shown that two doses of 1 c.c. each of toxoid, given at intervals of 6 weeks, confer immunity lasting at least 2 years. In the French Army the regulations make inoculation with toxoid compulsory; 2 c.c. of mixed T.A.B. vaccine and tetanus toxoid are given on three occasions at 3 weeks' interval.

2. CURATIVE.—Keep the patient as quiet as possible in a dark and noiseless room. Feeding may be impossible by mouth, in which event nasal feeding may be attempted, and if this, too, is impossible because of spasm, recourse must be had to glucose enemata. The vapour of chloroform is the best remedy by which to control severe spasms, and a mixture of chloral and bromide in full doses should be given between the chloroform administrations. A more or less continuous use of morphine or hyoscine is the alternative measure.

It is profoundly important that no delay whatever should occur in the use of serum. Injections of serum may be made subcutaneously, intramuscularly, intravenously, or intrathecally. The latter method achieves much easier access to the affected nerve cells, and is certainly preferable, though it is usually, and rightly, combined with other methods, the more gradual action of the antitoxin when given by the subcutaneous or intramuscular methods tending to balance the rapid elimination of that given intrathecally. A lumbar puncture is made, and 20 c.c. of cerebro-spinal fluid are replaced by an equal, or even slightly greater, quantity of a high titre antitoxin. In an acute case from 50,000 to 100,000 international units may usefully be thus given in the first few days, and subsequently the intramuscular or subcutaneous methods may be resorted to. Paterson, in Australia, has suggested much larger doses, in a scheme as follows: On admission, 200,000 units are given intravenously and 80,000 intrathecally. The intravenous dose is repeated after 12 hours and thereafter at 24 hours' interval. The intrathecal dose is repeated every 4 hours at first and is gradually reduced. Concurrently with these large doses of antitoxin, tetanus toxoid is also indicated. An immediate

dose of 1 c.c. of toxoid should be given as soon as the disease is suspected, and repeated after 4 days.

Less success has attended the therapeutic use of tetanus antitoxin than is the case with diphtheria antitoxin. This result is largely, if not entirely, accounted for by the relative slowness in the onset of symptoms in tetanus as opposed to diphtheria. The argument for the prophylactic use of antitoxin in every case of a wound contaminated with road material or soil contaminated with animal excreta becomes correspondingly strengthened.

ANTHRAX

Synonyms.—Wool-sorter's Disease ; Splenic Fever of Animals.

Definition.—An acute infective disease caused by the *Bacillus anthracis*. There are three clinical forms of the disease, according as the lesion is in the skin (malignant pustule), in the lung (pulmonary anthrax), or in the intestine.

Ætiology.—*B. anthracis* is a large Gram-positive bacillus possessing a capsule. On artificial media it grows in long filaments which, owing to the fact that the filaments do not readily break up into individual bacilli, tend to bend upon themselves and thus cause the outlines of the colony to assume a whorled appearance that is characteristic. Spores always develop in cultures in the presence of free oxygen.

In the tissues, however, the bacilli occur in straight rods measuring from 5 to 10 μ by 1 to 1·5 μ, the longer forms generally being found in attenuated cultures, and the bacilli found in the gelatinous œdema are usually longer than those found in blood. Spores never develop within the infected animal since free oxygen is necessary. The micro-organism is non-motile.

In the herbivora, especially sheep and cattle, the disease occurs epidemically and the infection assumes a septicæmic type. The spleen may be two or three times its normal size, and on section may be diffluent. An impression preparation from the cut surface shows enormous numbers of bacilli together with blood cells and mononuclear leucocytes. The liver and kidneys are in similar condition, and the lymphatic system is extensively involved.

The bacilli in the blood are invariably in the vegetative form, and it is only after being voided from the body that they produce spores, these being extremely resistant to adverse influences. It is claimed that spores may remain on the ground in a state of latent activity for as long as 12 years. But it is suggested by M. Fadyear and others that soil infection counts for little in this country, most cases being traceable to imported food stuffs, hides and brushes.

The carnivora are relatively immune, especially the dog.

Man occupies an intermediate position, and the disease is always communicated to him directly or indirectly from animals. Two principal forms occur, malignant pustule, a local infection through a cut or abrasion of the skin or a hair follicle, and wool-sorter's disease, an infection starting in the trachea and bronchi from the inhalation of dust containing spores.

Infections of the intestinal tract may occur but are rare. Such infections must originate from spores, as the bacilli do not withstand the action of gastric juice.

Bacteriological Diagnosis.—In a case of suspected malignant pustule direct microscopic examination will usually show the bacilli in the fluid in the surrounding vesicles. Sometimes examination of the sections of the excised malignant pustule is necessary. Cultures on agar will show in 24 hours the characteristic wavy-outlined colonies. Blood cultures in man never show the bacilli until just before death. Putrefaction rapidly destroys anthrax bacilli, hence the recognition of the bacillus in putrefying tissues entails careful bacteriological examination and animal experiments.

A guinea-pig may be inoculated with suspected material, and if anthrax be present will usually die within 2 days, and the bacilli may be demonstrated in the spleen.

Immunity.—Pasteur, noting that one attack of anthrax immunised an animal, elaborated a method of artificial immunity. He attenuated cultures by growth at 42·5° C. Sheep survived when inoculated with such cultures, and proved immune to a subsequent injection of a highly virulent living culture. By carrying out this process of active immunity the mortality among animals was greatly lessened. Marchoux showed that the serum of such animals conferred a certain degree of passive immunity; and Sclavo, by using a mixture of such immune serum and progressively attenuated cultures and virulent cultures, obtained very high degrees of immunity in the ass. Sclavo's serum is stable, and if given in quantities of 40 to 100 c.c. at an early enough stage in the disease is almost always successful.

Formerly the local effects of infection were considered due to the mechanical damage to the tissues by the rapid multiplication of the bacilli. Later it was considered that the tissues were injured by simple deprivation of oxygen. Now the result is considered to be a toxic phenomenon. There are three clinical forms of the disease.

I. Malignant Pustule.—The site of infection is nearly always upon an exposed part of the body—face or hands or forearms. The incubation period appears to be very short, perhaps not longer than a few hours. A small red papule forms, which rapidly becomes vesicular and then incompletely pustular. By the time vesication occurs there is a surrounding zone of intensely red œdema, becoming a brawny induration by the end of the second day. By this time a ring of secondary vesicles often surrounds the initial lesion, which has now formed a dry and almost black scab, generally raised above the surface of the affected skin. A frequent associated lesion in the case of the arm is lymphangitis, spreading upwards to the lymph glands, which become enlarged and painful. There is rarely much pain at the site of the initial lesion, though there is usually a good deal of itching and tenderness. Fever is almost constant, and in severe cases may be quite high. The patient is then very ill, with intense toxic symptoms. Mild cases occur, however, and in them both the local and the general symptoms are much less marked.

The prognosis turns upon the severity of the symptoms, especially of the toxæmic state. Death is sometimes very rapid—it may occur within the first week.

In some cases the initial papule and vesicle are ill-marked, but the attendant œdema is excessive (*malignant œdema*). The mortality in this type of the disease is a good deal higher than in the type in which the pustule is well formed.

II. Pulmonary Anthrax.—In this variety of the infection the bacilli are inhaled with dust from infected hair or wool. The result is the rapid development of fever, generally ushered in by a rigor, with very intense toxic symptoms and the signs of bronchitis. Cerebral symptoms develop, with great weakness. The whole course of the disease may be very short, even as brief as 24 hours. Recovery probably never takes place, even if the diagnosis has been made at an early stage.

III. Intestinal Anthrax.—This is probably the least common form of the disease. The infection is due to eating meat or drinking milk from animals suffering from splenic fever. The symptoms are those of a severe gastro-enteritis—fever, vomiting, diarrhœa and intense weakness. The spleen is enlarged. This form of the disease has been found to occur in small epidemics. The mortality is high, though not so high as in II.

Treatment.—(i.) Prophylactic.—This consists in the specific immunisation of animals subject to the disease, the complete destruction of dead bodies, and in the careful disinfection of all skins, hair and wool, before these are handled in any industrial occupation.

(ii.) Curative.—General measures (rest, etc.) are taken towards the prevention of a general infection. The pustule is kept clean, but is neither cauterised nor incised. A large dose of Sclavo's anthrax anti-serum (40 c.c. at least) is given as soon as possible by the intravenous route. This is repeated intramuscularly at intervals of 12 to 24 hours, the dose being gradually reduced. If the serum is not available, 0·6 to 0·9 g. of neoarsphenamine or one of its equivalents may be injected intravenously and repeated in 48 hours. Some observers consider this treatment to be as good as by serum for malignant pustule, provided it be given within 4 days of the onset of the disease. Treatment by sulphapyridine, given intensively (see pp. 16–17), has also proved successful.

GLANDERS

Definition.—An infectious disease, occurring not infrequently in the horse and in the ass, occasionally transmitted to man, and characterised by the formation of granulomatous nodules in the nose (glanders), and in the subcutaneous tissues (farcy).

Ætiology.—The *bacillus of glanders*, or *Bacillus mallei*, is a short rod, straight or slightly bent, of 3 to 4 μ in length by 0·5 to 0·75 μ in thickness. It is non-motile, and possesses no flagella, nor does it form spores. It can be cultivated on ordinary media at 37° C., but gives a more characteristic growth on potato.

The bacillus stains somewhat faintly with the usual aniline dyes, so that a mordant, such as carbolic acid, is usually employed, but even when deeply stained there is a tendency to decolorise rapidly. The staining is markedly irregular, this irregularity being a diagnostically helpful point. It is Gram-negative.

Pathology.—The disease chiefly affects horses, mules and asses—the latter being the most susceptible. Horned cattle are immune, but goats and sheep are occasionally infected.

In the horse, infection may take place through any abrasion of the skin, but most frequently through abrasion of the nasal mucous membrane from

infected water-troughs or feeding-mangers. The infection may be acute or chronic. In the acute form (glanders proper) there is fever and prostration, and in two or three days there occurs ulceration of the nasal mucosa with a sero-purulent discharge, leading on to involvement of the lungs, and death within a few weeks. In the chronic form—farcy—there is involvement of the lymphatic system associated with the original site of entry. The lymph vessels become enlarged—farcy pipes—and irregular thickenings—farcy buds—occur, which may soften and suppurate.

The disease may be latent, and can then only be diagnosed by the "mallein" test. In the human being the infection is generally derived directly from the horse, and is therefore usually confined to those in close connection with horses; but the disease has been contracted in the laboratory.

The *toxin* of *B. mallei* or mallein is an endotoxin, being derived from the bacterial bodies, in which respect it differs markedly from the toxins of tetanus and diphtheria bacilli. One of its chief characteristics is its resistance, it being capable of withstanding temperatures of 120° C. and prolonged storage with but little loss of strength. It is prepared by growing cultures in glycerin broth for 3 or 4 weeks, and sterilising these by boiling or autoclaving at 115° C. The cultures are then allowed to stand, and the supernatant fluid being decanted off, this is then filtered through a Chamberland filter. The resultant filtrate, to which one-half of 1 per cent. of carbolic acid is added, constitutes *mallein*. It contains the soluble portions of the bacteria, and substances from the altered medium, and is a similar product to tuberculin. It is used in doses of 1 c.c. to detect a glanders infection in the horse. As the reaction in a "glandered" animal is severe, both locally and constitutionally, it is unsuitable for use in man.

Forms of the Disease.—Both glanders and farcy have been known to occur in man in acute and in chronic forms. All forms are rare.

Symptoms.—1. Acute Glanders.—The incubation period varies, but is in most cases 4 days. At the site of infection in the nose there occurs an inflammatory swelling surrounded by œdema and lymphangitis, with a papular eruption soon becoming pustular. In a few days other and similar swellings appear, which soften and ulcerate, so that the mucosa of the nose becomes generally infected, leading to profuse muco-purulent discharge. The whole nose swells; it may be very considerably. The ulceration extends deeply so as to involve the cartilage and bone. The cervical lymph glands are usually enlarged and may soften, forming abscesses. Constitutional symptoms are present by this time, and death, usually with pneumonia, occurs about the middle of the second week.

2. Chronic Glanders.—This form resembles closely the disease as seen in the horse. There is a chronic profuse coryza, associated with widely scattered muscular and subcutaneous nodules. Unless the nature of the disease is suspected, it may go undiagnosed for some time.

3. Acute Farcy.—This is the form of the disease resulting from accidental inoculation of the skin. A local lesion of a highly inflammatory kind leads quickly to a spreading zone of lymphangitis, subcutaneous nodules (farcy buds) appearing in the track of the infection, softening and forming abscesses. The patient becomes severely ill, with symptoms of a general infection, and the course of the disease is of much the same duration as in acute glanders.

4. CHRONIC FARCY.—This only differs from acute in that the "buds" are associated with much less inflammatory reaction, the constitutional symptoms are much less severe, and the course of the disease is much longer. A few of the cases have extended over 12 months.

Diagnosis.—Acute glanders has been mistaken for small-pox, owing to the likeness of the papulo-pustular eruption to the specific eruption of this disease. The chronic forms are at times mistaken for the other infective granulomata (syphilis, tuberculosis and actinomycosis). Exact diagnosis turns upon bacteriological methods, direct or indirect.

The *bacteriological diagnosis* in man may be simple if a superficial swelling exists which may be opened. Direct cultures may be made therefrom, preferably on potato, and a rapid diagnosis made. It may be, however, that weeks elapse before such an opportunity occurs, or before some deeply situated swelling calls for operative interference. In such cases serum reactions, such as the complement-fixation test and agglutination, are indicated, and in a case watched by one of the authors the diagnosis was made by the opsonic test several weeks before the bacilli were cultivated from the tissues.

If material containing *B. mallei* be injected intraperitoneally into a male guinea-pig, tumefaction and suppuration occur in two or three days in the tunica vaginalis, and the bacilli can be recovered therefrom after about six days.

Treatment.—PROPHYLACTIC.—The utmost care must be taken in nursing, destruction of old dressings, etc.

The site of inoculation, if obvious, should be excised, and the underlying tissues should be treated drastically by strong antiseptics. All abscesses should be opened promptly and efficiently drained. The general symptoms are met by treatment similar to that given in any septicæmia.

TULARÆMIA

Synonym.—Deer-fly Fever; Pahvant Valley Fever; Ohara's Disease.

Definition.—A plague-like general infection of small rodents, hitherto confined to the United States, Japan and a district in Siberia; also recently in Norway, communicable to man. The disease has the peculiarity, in which it resembles Malta fever, of being extremely infective to laboratory workers handling the causative organism, *Bacterium tularense*, and attention to this aspect has been drawn by an important paper by Professor Sir John Ledingham and Dr. F. R. Fraser, in the *Quarterly Journal of Medicine*, vol. xvii., describing three cases occurring at the Lister Institute.

Ætiology.—In 1911 M'Coy, during plague work among ground squirrels in California, discovered a plague-like disease not due to *Bacillus pestis*, and in 1912 M'Coy and Chapin isolated the specific organism from the blood of infected animals, and it was named *Bacterium tularense*. Subsequently the organism was found in various rodents, and endemic centres of the infection have been recognised in various areas of North America. The first human case of infection appears to have been reported by Pearse in 1910, but bacterio-

logical proof connecting it with *B. tularense* was provided by Francis subsequently. Where the infection is endemic among rodents, human cases are not uncommon, and possibly some have recovered unrecognised. The infection is conveyed from animal to animal by various blood-sucking parasites. The fæces of infected bugs have been shown to be infective. Polluted water has recently been thought to be a source of infection in Norway and U.S.A. There is thus no difficulty in understanding how endemic centres of infection are kept up, and human infections in the field are readily understood. But it is difficult to explain the cases of infection in laboratory workers. It is suggested that a possibility is respiratory infection during the anæsthetising of experimental animals, when coughing is not uncommon, and the bacillus is certainly contained in bronchial secretions, as well as the excreta generally. The question appears to be parallel to the difficulty of explaining the great liability to laboratory infections with *Br. melitensis*.

B. tularense is a minute, Gram-negative cocco-bacillus, measuring, according to M'Coy and Chapin, 0·3, with a breadth of 0·2 μ. It is not easily stained by the ordinary dyes, unless a mordant, such as carbolic acid or aniline, is added. It is refractory to growth on ordinary media, the original cultures being obtained on a medium composed of egg-yolk. It will grow readily on serum glucose agar if a piece of rabbit spleen be added thereto.

Pathology.—In animals, nothing characteristic is found. At the site of inoculation some diffuse necrosis may be seen, and occasionally swelling of the corresponding lymph glands. The spleen, liver, lungs, and kidneys may show small necrosis areas. Human cases contracted in the field, probably from some blood-sucking fly, will show a local ulceration at the site of the bite, with swelling, and possibly suppuration, of the local lymph glands. Cases contracted in the laboratory provide no pathological data, for there is no evidence of the portal of infection, and the blood shows no characteristic changes.

Symptoms.—The infection expresses itself in two ways: (1) Dealers in rabbits may develop a necrotic papule, which is followed by acute lymphadenitis in the area affected. Suppuration may occur, with considerable pyrexia and toxæmia. (2) Laboratory workers studying the infecting agent have suddenly developed pyrexia, with marked malaise and no localising symptoms. The temperature subsided at the end of 3 weeks in the American series of cases, but it remained up for a longer period in the London series, and in one case there were irregular rises of temperature for a period of a year. The marked features of the majority of the cases were the malaise, the recurrent nature of the fever, and the prolonged inability to work.

Diagnosis.—In endemic areas, people handling rabbits and other rodents, who develop fever, with or without localising signs of insect bites, should be under suspicion. In this country, only laboratory workers are likely to be infected. In either case, the diagnosis depends upon specific agglutination of *B. tularense* antigen. Very definite agglutinations were noted towards the end of the second week after the commencement of the disease, and the titre rose rapidly and remained high during the long convalescence.

Prognosis.—This appears to be of about the same order as that in Malta fever. The disease is not fatal, but causes a long period of inability to work.

Treatment.—No account is given of any attempts to confer immunity,

either prophylactic or phylactic, and the treatment would appear to be one aiming at rest, with measures to counteract the anæmia that tends to supervene.

SCARLET FEVER

Synonym.—Scarlatina.

Definition.—An acute specific fever of sudden onset characterised by faucial inflammation, a punctate erythema of the skin, and a tongue at first furred but later raw with prominent red papillæ. Desquamation follows, and inflammatory sequelæ may occur, involving especially the ears, cervical glands and kidneys.

Ætiology.—Scarlet fever is a disease of temperate climes and seldom gains a foothold in tropical or subtropical countries. It is endemic in large cities and populous centres, tending to flare up every few years in local epidemic form owing to the accumulation of susceptible material. Its general epidemic prevalence, however, is irregular, and no definite periodicity has been recognised. In the United Kingdom it is prevalent in the latter part of the summer and reaches its maximum at the end of the autumn; the period of least prevalence being the spring. Of late years, although the incidence has not appreciably declined, the mortality has fallen and the type of case become less severe. Severity, however, still varies greatly in different years and in different localities.

The case mortality of scarlet fever (proportion of deaths to attacks) is not more than 0·5 or 2 per cent. It is greatest in the first year of life and diminishes with age. Females are more liable to infection than males, but attacks in males are rather more likely to terminate fatally.

Of predisposing causes, childhood and the absence of acquired immunity are the most important. Infants under one year of age seldom contract the disease. The maximum incidence occurs during the fifth and sixth years of life, a period slightly later than is the case with such diseases as whooping-cough and measles. Adults are not exempt, but scarlet fever is rare in the aged. As a rule, one attack protects permanently, but second attacks do undoubtedly occur. Multiple recurrences should probably be referred to some other cause than scarlet fever.

Poverty, by entailing shortage of food, overcrowding, and defective isolation facilitates the spread of the disease and augments its death-rate.

The infective agent resides in the mucous secretions of the nose and throat and in the secondary suppurative lesions. The disease is infectious from its commencement, but the exact duration of infectivity cannot be determined for any given case. Six weeks' isolation is generally sufficient if by that time the mucous membranes are healthy and the skin free from sores. Many authorities reduce this period to 4 weeks for mild and uncomplicated attacks. Desquamation is not regarded as dangerous unless the scales are contaminated by the patient's discharges, and the infectivity of urine which remains albuminous has never been proved. The infectivity of scarlet fever is not nearly so great as that of measles, varicella or small-pox.

In most cases infection is by droplets derived directly from a person suffering with, or recently recovered from, the disease, but transmission by infected fomites or infected milk may also occur. Aerial infection by dust is possible. It is an important fact that discharges from the nose, throat, mouth and ear may remain infectious for many weeks, and pre-existing purulent discharges also become infectious when scarlet fever is contracted. The occurrence of catarrhal infection of the nose or throat in a scarlet fever convalescent may lead to a recrudescence of infectivity.

Intermediary carriers have on occasions spread the disease without themselves showing signs of infection. On rare occasions, too, convalescents, although apparently healthy, have for months remained capable of transmitting the fever. The infectivity of carriers appears to be intermittent, and the receptivity of those exposed is increased by close contact, debilitating circumstances or acute disease, of which diphtheria may be cited as an example. Attendants on scarlet fever cases, although long immune, may finally contract the disease.

Infected milk may be responsible for localised and, sometimes, for more widespread outbreaks of the fever. In most instances the milk has been infected from a human source, but possible derivation of infection from cows with ulcerated udders and teats is suggested by the well-known Hendon outbreak. Scarlet fever is not known to be transmitted by water or by sewage. Cases of wound infection are not numerous, but puerperal scarlet fever is well recognised.

Pathology.—Klein, in 1887, isolated a streptococcus from the teats and udders of cows at Hendon, and considered it the causal agent in a milk-borne epidemic of scarlet fever. It was customary, however, to regard the streptococci found in the throats and tissues of scarlatinal cases as secondary invaders, it being impossible to grow these organisms from the blood of patients suffering from the fever in its toxic, and presumably uncomplicated form.

Drs. George and Gladys Dick, of Chicago, however, produced evidence that scarlet fever is a *local* infection of the throat by a hæmolytic streptococcus, and attribute the general symptoms of the disease to toxins absorbed from the local focus. They have infected patients with scarlet fever by swabbing the fauces with a pure culture of their organism and have elaborated a test analogous to the Schick test in diphtheria. This is the *Dick test*. It is made by the intradermic injection of 0·1 c.c. of a 1 in 1000 dilution of toxic broth filtrate in saline solution. Boiled filtrate is used as a control. An erythema at the point of injection, maximal in 24 hours, indicates susceptibility to scarlet fever. The same types of reaction occur as in the Schick test (*q.v.*) but in the Dick reaction the erythema is not indurated. During the first few days of scarlet fever a positive result may be expected, but the test may prove negative for some days after the administration of anti-scarlatinal serum. A few convalescents remain positive to the test, the majority become negative. The new-born infant of a susceptible mother is usually Dick-positive.

Griffiths has shown that the hæmolytic streptococci of scarlet fever are members of a group comprising many different serological strains.

Susceptible persons can be immunised by subcutaneous injection of increasing doses of scarlatinal toxin at intervals of 7 days. For adults four

or five injections are required, commencing with 500 "skin test" units and ending with a dose of 50,000, 80,000, or even 120,000 units. The skin test unit of scarlet fever toxin is the smallest amount which gives a standard positive reaction in persons susceptible to scarlet fever, and a negative reaction in persons immune to the disease. The standard reaction is the appearance within 24 hours of an area of erythema not less than 1 c.m. in diameter. If too large an initial dose of immunising toxin is given, a transitory "miniature scarlet fever" may result, but this is rare. The simultaneous injection of 2 or 3 minims of 1 : 1000 adrenaline chloride solution prevents serious reactions. Immunity develops more slowly than in the case of diphtheria, and its duration is indefinite but prolonged. If the Dick test proves positive 6 months after, a further injection is recommended in the case of those nursing scarlet fever.

By immunising horses, an antitoxic serum is produced, which may bring about a rapid amelioration of the toxic symptoms of scarlet fever, but has little influence in preventing complications.

Schultz and Charlton pointed out that intradermic injection of 1 c.c. of the serum from a patient convalescent from scarlet fever will, in a few hours, cause a local blanching of the rash of the fever. This is known as the blanching test. W. Mair suggests that the test is due to antitoxic immunity in the donor, which will account for its occasional failure, and also the fact that the serum of some donors not known to have had scarlet fever, will give the reaction. The antitoxin prepared from the Dicks' scarlatinal streptococcus possesses the same blanching property, and now is used for the test.

The post-mortem appearances in scarlet fever are not distinctive. The rash, unless hæmorrhagic, disappears after death. Such gross changes as are found in the fauces, cervical glands, lungs, heart, kidneys and liver, together with moderate enlargement of the spleen and lymphoid structures, merely indicate an acute infective process. In severely toxic cases, early decomposition with much post-mortem staining of the tissues, fluidity of the blood and subserous ecchymoses, indicate the intensity but not the nature of the infection. In cases surviving longer, inflammations of the lungs, serous sacs, endocardium, pericardium and joints may possibly be present, and desquamation may be recognised. Scarlatinal nephritis is described as being essentially glomerular in type, but other parts of the kidney are also involved.

Symptoms.—The incubation period is short, the period which elapses between infection and the development of the first symptoms being from 2 to 4 days, with an average of 72 hours, or 4 days from exposure to rash.

Invasion is abrupt, the cardinal symptoms being vomiting, headache and sore throat. In some severe cases vomiting may be so urgent as to suggest irritant poisoning, especially if accompanied by diarrhœa; in mild cases vomiting may be absent. Rigor is uncommon, convulsions occasionally occur in children. Cough and catarrhal symptoms are decidedly rare, but a mild conjunctival injection is not unknown. The skin is hot and dry, the cheeks flushed, and the eyes bright. The limbs ache, the appetite is in abeyance, and the tongue rapidly becomes coated with white fur, through which the papillæ project as red points (*strawberry tongue*). Slight nocturnal delirium is common. The temperature rises rapidly, and even on

the first day may reach 103° or 104° F. An undue acceleration of the pulse is usually a marked characteristic, rates of 160 or more are common in young children, and rates of 120 to 140 in adults.

Very mild cases often occur, and in these the symptoms of invasion may be absent, the rash being the first indication of the disease.

Uniform injection of the tonsils, fauces, and uvula is present in the early stages of the disease. Later, the injection becomes more vivid, the tonsils are swollen, and a distinct follicular exudate often appears; inflammatory œdema of the fauces soon makes its appearance in severe cases, and may be accompanied by free mucous secretion. The tonsils may become covered by a thin necrotic film, or a more or less coherent exudate may form which may encroach on the faucial pillars and base of the uvula, and closely simulate the membranous exudate of diphtheria. In the more severe forms of scarlet fever, the tonsillar and faucial inflammation is very intense, and both ulceration and sloughing occasionally occur; thick muco-pus trickles down from the naso-pharynx, the nasal sinuses are invaded, and acrid discharge blocks the nostrils and excoriates the upper lip. The respiratory obstruction is especially severe if adenoids are present. In severe cases, inhalation broncho-pneumonia is a decided danger.

A punctate injection may often be seen on the soft palate and adjacent part of the roof of the mouth even before the appearance of rash on the skin, and is of diagnostic value. The eruption usually appears within 24 hours of the invasion, but may be delayed sometimes for several days. It appears first on the upper part of the chest, the root of the neck and the upper arms as a finely punctate erythema; sometimes it is first seen in the axillæ. It quickly spreads to the trunk and limbs, reaching the legs last. The cheeks are merely flushed, and the existence of an area of circum-oral pallor is a well-known and striking feature. The thick skin of the palms and soles is also in most instances free from the distinctive rash. The eruption often shows a symmetrical intensification in certain regions, such as the lower abdomen and groins, the inner aspects of the thighs, the axillæ, the back, and the points and flexures of the elbows and knees.

Of the two elements of the rash, one is minutely punctate, the other erythematous. It is the former which gives it its distinctive character. On coarse skin the puncta are particularly large. When the erythematous element is intense the skin may actually appear œdematous and the puncta be quite obscured. In such cases, on subsidence of the rash, yellow staining may be apparent. In addition to punctation and erythema, minute petechiæ or small linear hæmorrhages are sometimes seen in the flexures of the elbows (*Pastia's sign*), groins, wrists and knees. By application of a tourniquet to the upper arm, petechiæ may be rapidly produced at the flexure of the elbow. This is the *Rumpel-Leede phenomenon*. It may also be positive in measles, purpuric states and peliosis rheumatica. These hæmorrhages remain when the rash has faded, and together with coarse injected papules on the outer sides of the arms and legs afford valuable evidence. The rash on the buttocks and extremities may assume a slightly blotchy papular appearance, and so bear a distant resemblance to that of measles. Minute sudamina sometimes accompany the rash, giving rise to the variety known as *scarlatina miliaris*. Itching is not common, and urticaria is rare, but in some cases accompanies or precedes the outbreak of the rash.

The rash may be quite transitory or may last a week or even longer. Generally speaking, it is more pronounced in severe attacks, but sometimes attacks which are quite mild show rashes of considerable intensity and persistence. A dusky, blotchy, morbilliform eruption, generally limited to the convexity of the knees and elbows, but sometimes more widespread, may supervene in grave cases. It is known as the *septic rash.*

At the time of the initial faucial inflammation the glands at the angles of the lower jaw are swollen and tender. During the eruptive period a moderate enlargement of the axillary and inguinal glands, sometimes of the posterior cervical glands as well, is often to be detected. The spleen is rarely to be felt. At times the glandular swelling leads to confusion with rubella, but the glands do not attain the size or show the marked tenderness characteristic of the latter disease.

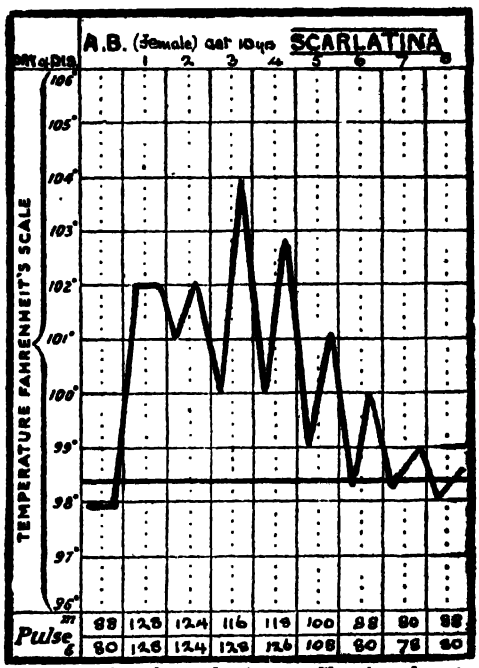

FIG. 1.—Simple scarlet fever. Showing abrupt onset and rapid lysis.

In an average case a rapid rise of temperature (Fig. 1) marks the invasion, but the maximum may not be attained until the full development of the rash on the third or fourth evening, when readings of 103°, 104° or even 105° F. may be registered. Slight morning remissions occur. The fall is by lysis, reaching the normal by the fifth or sixth day of the disease. Termination by crisis is unusual. In bad cases of a septic type, the fever is prolonged, with increasing daily oscillations as septicæmic symptoms become prominent. In the malignant or toxæmic type of the disease, the fever is higher from the first and shows less remission, but occasionally is subnormal throughout. A protracted remittent fever may occur in scarlet fever without local symptoms or complications to account for it; this variety is sometimes known as the "typhoid type."

Abrupt rises of temperature during the convalescent period may signalise the onset of such complications as adenitis, otitis, nephritis, endocarditis, empyema, or a metastatic abscess. Sometimes such pyrexial attacks occur without ascertainable cause, but a thorough examination of the patient is always necessary. Very mild cases of scarlet fever without obvious febrile disturbance certainly exist.

Desquamation is a well-known characteristic, but the degree to which it

occurs is very variable. The tongue peels in patches or strips, and by the fourth day is raw with prominent papillæ (*raspberry tongue*). The flushed cheeks begin to shed a fine powder during the febrile period. Fine peeling of the lobules of the ears, of the margins of the lips, and of the skin at the root of the neck, possibly also above the pubes, next makes its appearance. By the end of the first week, peeling is generally well marked on the neck, chest, inner sides of the arms, and possibly on the trunk. Within a fortnight it may be seen on the hands and possibly on the feet. It may not be complete on the latter until over 6 weeks from the onset of the fever. Partial re-desquamation often occurs on the soles and is not infectious. The characteristic of the desquamation is the pinhole or ringed form in which it commences, the horny layers of the skin being shed first over the summits of the papillæ, forming apertures which enlarge centrifugally and fuse with their neighbours. Where the skin is thick, as on the hands and feet, it tends to separate in larger flakes, or may even be thrown off in the form of incomplete casts. A rather characteristic form of peeling is sometimes seen on the finger-tips when separation begins, as a split parallel to the free edge of the nail.

In severe cases considerable loss of hair may accompany or follow desquamation, but is temporary only, at all events in the younger patients. Furrows may also appear across the nails and take several weeks to reach the free edge.

Although desquamation typically proceeds as described above, there are cases of true scarlet fever where it is insignificant. It is unsafe to pronounce definitely against scarlet fever until 3 weeks have elapsed. In doubtful cases the hands and feet should be watched with care. A change to negative in the Dick test is confirmatory. A dry powdery appearance of the palms and soles is sometimes the sole indication of peeling. During desquamation the skin may appear harsh, dry, cracked or even eczematous.

A polymorphonuclear leucocytosis makes its appearance shortly after infection and reaches a maximum with the full development of the rash. It persists a variable time. A unique feature in favourable cases is an increasing eosinophilia during convalescence. Fluidity and slow coagulation of the blood are indications of severity, but apart from this blood examination has little prognostic value. Döhle has described certain bodies seen in the polymorphonuclear leucocyte when stained by Leishman's method as being characteristic. They appear in the acute stage as more or less definite blue spots in the cytoplasm of the cells. They are, however, not exclusively found in scarlet fever.

VARIETIES.—These are: (*a*) Simple or Benign; (*b*) Septic or Anginous; and (*c*) Toxic or Malignant. Surgical or Wound Scarlet fever and scarlet fever occurring during pregnancy or the puerperium, also have special characteristics.

Simple scarlet fever is characterised by an onset of moderate severity in which the initial vomiting is not repeated and sometimes is absent. The faucial inflammation is slight, and the temperature, which may reach 102° F., has almost reached its acme in 24 hours; generally the climax is reached by the third day and amelioration of symptoms is then rapid. The urine may be normal throughout, or a trace of albumin may accompany the febrile disturbance. By the third or fourth day the tongue, at first slightly coated,

has peeled, and slight powdering may be evident on the cheeks. Convalescence is rapid.

The *septic or anginous* variety comprises most of the severe and fatal cases. It is characterised by intense faucial inflammation and a tendency to the development of septicæmic manifestations. Repeated vomiting, sharp diarrhœa and prostration may signalise the onset. The faucial inflammation is either severe from the first or unexpectedly becomes so after a lapse of 2 or 3 days. The tonsils are much swollen and a patchy or coherent membranous exudate may form. Rapid and destructive ulceration of the tonsils, soft palate and its pillars sometimes occurs. The mucous membrane of the mouth may be excoriated and bleed at the slightest touch. The pharynx, and even the upper aperture of the larynx, may become involved in the inflammation, although, as a rule, implication of the latter is more suggestive of diphtheria than of scarlet fever. The discharges from the throat excoriate the angles of the mouth and a purulent acrid rhinorrhœa irritates the nares and upper lip. Deglutition is painful, respiration is obstructed, and the patient often sleepless, restless and later delirious. The cervical lymph glands become swollen and tender, and peri-adenitis or extensive sloughy cellulitis of the neck may ensue. This sometimes gives rise to fatal hæmorrhage by eroding large veins or even an artery. Cyanosis and coldness of the extremities and cardiac dilatation are common. The rash is generally intense, dusky and blotchy. The temperature often reaches 104° or 105° F. in the early stages of the disease, and pyrexia may persist long beyond the ordinary period and, changing its type, assume a remittent or intermittent septicæmic form.

Death may occur in the first week; more often life is prolonged into the second week, by which time circulatory failure becomes pronounced; hypostatic congestion of the lungs or spreading broncho-pneumonia occurs. Otitis, arthritis, suppurations of the serous sacs, endocarditis, or nephritis may appear as complications, and a true scarlatinal pyæmia be evident.

Many patients show septic symptoms of a much milder type and make good recoveries. In grave cases which recover, improvement is very gradual and usually sets in towards the end of the second week, but may be later.

Toxic or malignant scarlet fever is characterised by a toxæmic condition out of all proportion to the degree of inflammatory reaction in the throat. Such cases are marked by high fever, cerebral disturbance, profound prostration and circulatory failure. The rash is often petechial, but in the most severe attacks the patient may die before it has time to appear, and the real nature of the disease may only be revealed by the supervention of scarlet fever in contacts. The throat may be intensely injected, but the œdema, ulceration and thick purulent secretion which characterise the septic variety may be absent altogether. Sometimes convulsions precede death, but mostly delirium merges into coma. Rarely, however, the patient dies of circulatory failure with vomiting, prostration and extreme pallor, but with clear intellect, suggestive of the type of death seen in some cases of diphtheria.

Sufferers from the malignant type of scarlet fever mostly succumb within a week of the onset, sometimes within 24 hours. But, as in the septic form, cases of the toxic or malignant type are not now so common or characterised by such extreme malignancy as was formerly the case.

Rarely scarlet fever assumes a purpuric form, with bleeding into the skin

and sometimes from the mucous membranes also. This complication makes its appearance towards the end of the second or during the third week, and often proves fatal. It is possible that some of the cases formerly described, where hæmorrhages occurred early in the eruptive stage of the disease, were really hæmorrhagic small-pox with prodromal rashes of scarlatiniform character.

Surgical scarlet fever may be a sequel of operations, wounds or burns and scalds. It is often seen after operations on the nose and throat. The incubation period is short, often less than 3 days, and the rash may make its first appearance round the wound. Faucial inflammation save in throat cases is often slight, and faucial swabs may be negative. The infected wounds show a great tendency to suppurate. If the infection starts from a wound or abrasion on a limb, injected lymphatic vessels are often evident which show a characteristic punctate rash. The corresponding lymph glands are enlarged and tender. When the fever follows burns or scalds the incubation period is also short and the accompanying angina may be slight. Cases of surgical and of burn scarlet fever where the throat is not especially involved are not highly infectious. They are often left in general wards with impunity, but there is no doubt that occasionally they spread the infection.

Scarlet fever may arise in the pregnant woman. In early pregnancy it is rare, and is said not to lead to abortion ; but occurring later it is very prone to produce abortion or premature delivery. When the infection occurs either immediately before or immediately after labour, it is apt to assume a grave form with a very high mortality from septicæmia ; but there is no doubt mild attacks may occur even at this period.

Anomalous forms of scarlet fever occur in which one or more of the cardinal symptoms are lacking. In some only sore throat is recognised (*Scarlatina sine eruptione*), and yet the patient may transmit the typical disease. The cases of infectious sore throat which often herald outbreaks of scarlet fever belong to this category. In others the rash is so ephemeral or atypical that its true nature escapes recognition ; in yet others, the rash is the most pronounced feature, both fever and sore throat being insignificant. In cases where the rash is very scanty or insignificant, desquamation may not be at all marked.

Complications.—These may be divided into two groups ; those which arise locally in connection with the faucial and pharyngeal inflammation, and those of a general or more remote character. To the first group, in order of frequency, belong otitis, cervical adenitis, rhinitis, secondary tonsillitis and stomatitis, and aspiration broncho-pneumonia. The second group includes rheumatism, albuminuria, nephritis, endocarditis, pericarditis, pleurisy and empyema.

In severe cases complications show a great tendency to occur in combination rather than singly.

Otitis.—This is met with in from 10 to 15 per cent. of the cases, and is an inflammation of the whole mucous tract of the middle ear. Its greatest frequency is in childhood, and its incidence is favoured by the presence of adenoids. It is more common in severe cases, and may show itself by the end of the first week of the fever or later. It is often bilateral. Earache with an injected and bulging tympanic membrane are the signs to be expected, but sometimes a free discharge of muco-pus or pus and blood from the ear is the

earliest indication. Unexplained pyrexia not due to fresh faucial or glandular extensions or to one of the distant complications should always lead to a careful examination of the ears. Perforation generally occurs in the upper part of the tympanic membrane. Deafness may occur, but fortunately is transient in most cases. Pain and tenderness with slight œdema of the mastoid appear in some instances, and may be accompanied by restlessness, vomiting and fluctuating temperature. The intensity of these mastoid symptoms may vary from day to day. In children the mastoid air cells are very superficial, and pus easily makes its way beneath the covering periosteum.

Sometimes the labyrinth becomes implicated. In such cases deafness, vomiting, vertigo and nystagmus may occur. Labyrinthine deafness may be permanent.

Such intracranial complications as meningitis, extradural abscess, lateral sinus thrombosis, cerebellar or temporo-sphenoidal abscess, belong to the more chronic forms of ear disease, but occasionally they arise during the acute stage. Persistence of mastoid tenderness with some local headache and slight fever may be the only signs of inflammatory mischief invading the dura in the vicinity of the lateral sinus.

In most instances scarlatinal otitis subsides in a few weeks and the perforation of the membrane closes.

Secondary Adenitis.—A rapid and considerable swelling of the upper cervical lymph glands may occur during the convalescent stage of the fever. The swollen glands are usually those behind the angle of the mandible or higher up under the insertion of the sterno-mastoid muscle. The adenitis generally supervenes during the second, third or fourth week of the disease. It is marked by local tenderness and a sharp accession of fever. In favourable cases the temperature becomes normal in a day or two and the glandular swelling rapidly subsides, but suppuration may ensue.

Secondary tonsillitis should suggest the possibility of diphtheritic infection. Peritonsillar abscess may also occur. Ulcerative stomatitis with much fetor of breath and sometimes even sloughing of soft tissues and necrosis of bone are also looked upon as secondary infections. Vincent's organism and diphtheria bacilli should be sought for in such cases.

Rhinitis.—Acrid or purulent rhinorrhœa is characteristic of septic attacks. The air sinuses may become infected. A rhinorrhœa which occurs in the later stages of the fever is often responsible for the transmission of infection. True diphtheria bacilli are more frequently found in the nasal than in the ear discharges of those suffering from scarlet fever.

Nephritis.—Slight albuminuria during the eruptive stage of scarlet fever is transitory and of no great importance, but about the third week nephritis may supervene. It is to be expected in a little over 3 per cent. of the cases, and is more common in severe than in mild attacks. Chill, damp and exposure favour its incidence. The onset may be insidious or fulminant. In the insidious cases albuminuria, at first slight, and even intermittent, is the first sign. In the fulminant cases, headache, vomiting, pyrexia and even rigor may mark the onset. The urine becomes heavily loaded with albumin, casts and blood, and there is more or less suppression. The temperature may rise gradually or suddenly and show marked daily remissions. Lumbar pain is uncommon, but abdominal pain and constipation are marked features of some attacks. The amount of dropsy is very variable; it may be con-

siderable in ambulant cases. Anæmia is of rapid onset and very pronounced. The pulse tension is raised and cardiac hypertrophy is soon established, sometimes dilatation ensues. In a favourable case some improvement occurs within a week, the secretion of urine increasing, but the hæmaturia and albuminuria take much longer to clear up. In some cases albuminuria persists and chronic interstitial nephritis may ensue. The duration of an average attack may be put at 7 weeks, but is subject to much variation. Broncho-pneumonia, pulmonary œdema, œdema of the glottis, and uræmic symptoms occur in severe cases. Convulsions may be recovered from, but coma is of bad augury.

In the septic type of scarlet fever sharp hæmaturia with casts and streptococci may accompany other pyæmic manifestations.

Rheumatism.—This is common, and usually makes its appearance towards the end of the first week. The arthritis is fleeting and mostly involves the hands and wrists. Joint effusions are not always present. The temperature is raised. Sometimes the endocardium and pericardium are implicated, as in ordinary rheumatism, but the profuse sweats and creamy tongue are absent. Scarlatinal rheumatism is more common in adolescents and adults than in children. A mono-articular or multiple suppurative arthritis with, it may be, other pyæmic manifestations is sometimes seen.

Cardiac complications.—There are three groups: those due to toxæmia; those secondary to rheumatic or pyæmic complications; and those accompanying nephritis. The toxæmic effects are cardiac dilatation and acceleration of the pulse, which are so characteristic of this fever.

Scarlatinal rheumatism is occasionally the precursor of simple or more rarely of malignant endocarditis. An unfortunate feature is the tendency to pick out the aortic valves. The influence of nephritis in producing rapid cardiac hypertrophy or inducing dilatation has already been mentioned. Pericarditis may occur quite early in some cases of the septic type. The effusion is generally purulent.

Pulmonary complications.—Neither bronchitis nor broncho-pneumonia is common, but aspiration broncho-pneumonia may complicate septic cases. Œdema of lungs may arise during the course of acute nephritis. Lateral sinus pyæmia may give rise to pyæmic infarction of the lungs, empyema and even pneumothorax. A primary empyema, often of insidious onset, occurs in some patients. Lobar pneumonia is rare; occurring early in the disease, it is streptococcal in nature and the prognosis is very grave.

Streptococcal peritonitis is a very rare event.

Nervous complications.—If the delirium of onset, the nervous manifestations of uræmia and the cerebral complications of otitis be excluded, it may be said that nervous disturbance during the course of scarlet fever is rare. In those predisposed, epileptic fits may signalise the invasion. Hemiplegia with convulsive onset, incomplete paraplegia and peripheral neuritis have all been described. Chorea develops occasionally, usually in association with arthritis and endocarditis. Tetany sometimes occurs. Mental disturbance of a maniacal or melancholic type is an infrequent sequel, or may show itself during the acute stages.

On rare occasions gangrene of the extremities has been encountered. It is sometimes embolic in origin and leads to mummification, but gangrene has also been described in association with purpura and in

congenital syphilis. Post-scarlatinal diphtheria was, in pre-antitoxin days, one of the gravest complications. Diphtheria may develop at the onset of the fever, but more often appears during early convalescence. It occurs more often in hospital-treated cases than in others. Every throat inflammation about the nature of which there is the slightest doubt should be subjected to bacteriological examination at once. This is a more rational procedure than the indiscriminate injection of all scarlatinal patients with diphtheria antitoxin. All nasal and ear discharges should also be bacteriologically examined.

Relapse and Reinfection.—A recurrence of the fever and rash before complete recovery from the initial attack occurs in from 0·5 to 7 per cent. of the cases. In hospital it is not uncommon for the original infection to be replaced and protracted by one of different serological type.

Diagnosis.—Bacteriological identification of the *Streptococcus scarlatinæ* is not sufficiently easy to afford much help in diagnosis. A positive Dick test before the third day of the attack is in favour of scarlet fever (it should become negative later) but a negative result does not exclude it. A positive Schultz-Charlton blanching test, made by the intradermic injection of 0·2 c.c. of a 1 in 10 dilution of immunised horse serum applied to the newly developed rash, preferably on the lower abdomen, is of more value. The reaction takes 8 hours to develop, and attains a diameter of 3 c.m. or more. The chief difficulty arises with mild attacks and with patients who come under observation after the initial stage. In the former the rash is evanescent, constitutional disturbance slight, and the tongue often atypical. A history of a previous attack is of great weight, but diagnosis can only be confirmed by the supervention of desquamation or of some characteristic complication. Sometimes the infection of a contact gives the clue. In days immediately following the rash significant signs are: slight staining of the trunk, faint striæ in the flexures of the elbows, knees and groins, or a triangular patch of punctate erythema over Scarpa's triangle. The submandibular glands may be enlarged, and coarse papules resembling goose-skin present on the outer aspects of the arms and legs. The tongue has usually peeled by the fourth day and remains raw and papillated for about a week. Slight albuminuria, in the absence of diphtheria, is significant.

Desquamation of the typical pinhole type rarely occurs in other conditions than scarlet fever; the character of the accompanying symptoms and the time of appearance of the peeling must be taken into consideration.

Simple tonsillitis is distinguished by the absence of punctate rash, a tongue which remains heavily coated, and absence of desquamation. But an erythema may be present, with fleeting muscular pains and sometimes otitis, and even endocarditis or nephritis may occur as complications.

Careful scrutiny of the body for a rash will usually prevent confusion with *diphtheria*. When faucial exudate is present in scarlet fever, it is usually softer and less coherent than in diphtheria, and any grey ulcerated areas are depressed below the general surface. In scarlet fever, too, the faucial pillars and soft palate may show the punctate rash, whilst pallor of the throat is more distinctive of diphtheria. In scarlet fever, febrile disturbance is more marked, initial vomiting is common, and delirium may occur. The fugitive erythema which sometimes appears on the chest in diphtheria is not

punctate. Bacteriological examination is decisive, but the two diseases may coexist.

When *influenza* is rife, cases of scarlet fever are apt to be overlooked; but in influenza rashes are exceptional, and careful observation of the progress of the disease will soon lead to a correct diagnosis.

Lobar pneumonia may, in children especially, by its abrupt onset, high fever, vomiting and faucial inflammation, give rise to suspicion of scarlet fever, a suspicion favoured by the flushed face and circumoral pallor which may be present. But the throat affection is trivial, the respirations are rapid and accompanied by action of the alæ nasi, and there is no punctate rash on the chest. Sooner or later consolidation of the lung may be detected, often in such obscure cases at the apex or high in the axilla.

Food, drug, serum and enema rashes often cause difficulty. Of drugs the most important rash-producers are copaiba and similar oleo-resins, quinine, phenazone, the salicylates, aspirin and belladonna. Arsphenamine compounds and sulphonamides may also do so. Anomalous distribution or polymorphic character of the rash should at once arouse suspicion, especially so the discovery of urticarial wheals. The history and accompanying symptoms are of importance.

Erythema scarlatiniforme is characterised by a punctate eruption which is sometimes patchy and confined to the trunk. The rash is remarkably persistent, and desquamation may ensue whilst it is still in the florid stage. The peeling is profuse and the subjacent skin often erythematous. The characteristic sequelæ of scarlet fever are wanting. The disease is not known to be infectious and is very apt to recur, which gives a clue to its recognition. *Acute exfoliative dermatitis* is by some regarded as identical with it.

German measles in the scarlatiniform stage closely resembles scarlet fever. The diagnosis turns on the trivial character of the accompanying symptoms, which are chiefly catarrhal, and the tender swelling of the posterior cervical mastoid, and occipital glands. Even when the rash is scarlatiniform on the trunk, distinct morbilliform elements may often be recognised about the wrists and on the lower extremities, and this, with the history of an initial spotty rash on the face and around the mouth, is of great significance. The eyes are suffused and subsequent desquamation is insignificant. Sequelæ are practically unknown.

Measles is more easily distinguished. The rash is different and invades the face. Catarrhal symptoms are pronounced and Koplik's spots are present. Difficulty is only likely to arise in those cases of scarlet fever where a blotchy rash is present, or where the appearance of a septic rash may simulate intercurrent measles.

Prodromal rashes of a scarlatiniform type may appear in small-pox, chicken-pox and measles. In small-pox, the punctate rash is usually confined to the bathing-drawers area and to the axillæ. Sore throat is in favour of scarlet fever, whilst rigor and severe lumbar pain suggest small-pox. The eruption of the latter disease appears on the third day, and a doubtful case should always be isolated over that period. The initial rashes of small-pox are said to be absent in children under 10 years of age.

The eruption of chicken-pox may be preceded by a rash which is scarlatiniform, but it is more likely to be erythematous. The diagnosis turns on the

condition of the fauces and tongue, the absence of the other signs of scarlet fever, and the speedy appearance of the characteristic vesicles.

As a prodromal rash in measles, a scarlatiniform eruption is decidedly rare. The marked catarrhal symptoms which accompany it will arouse suspicion, which is confirmed by the discovery of buccal inflammation and Koplik's spots.

Prognosis.—The mortality of scarlet fever varies with the type of the prevailing epidemic. Of late years, in Great Britain, a mortality of less than 1 per cent. has been the rule. Of other factors, age is the most important, the mortality being greatest in infancy, diminishing rapidly after the second year, and continuing to fall until puberty is reached, the least fatal period being from puberty to 36, after which age a slight rise occurs. The death-rate is slightly higher in males than in females. Tuberculous infections are likely to be lighted up by the infection, and puerperal patients run a grave risk of septicæmia. Chronic renal disease, if present, is likely to be adversely influenced.

Malignant attacks are very fatal, and the septic type of attack is also very serious, especially if broncho-pneumonia supervenes. In adults, marked sleeplessness and delirium are unfavourable signs, and in children, convulsions occurring after the initial stage. With regard to complications, nephritis in many instances clears up, especially if detected early and properly treated. Grave symptoms are uræmic convulsions, coma, repeated vomiting and suppression of urine. Œdema of lungs often precedes the fatal issue.

Of other complications, pericarditis is the worst. It is often purulent and may be associated with empyema. Hemiplegia, if of vascular origin, mostly becomes permanent. The danger of otitis media is remote rather than immediate.

Treatment. — PROPHYLACTIC. — Infectivity ceases mostly within a period of 6 weeks. A negative throat culture does not always indicate cessation of infectivity, and this test is not employed as a routine measure. Late desquamation of the hands and feet is not a source of infection, but discharges from the nose, throat or ear are dangerous. Convalescent carriers are responsible for something less than 3 per cent. of the cases treated in fever hospitals. The dangerous carrier is often characterised by unhealthy conditions of the nose, throat or ear, discharges from which may have reappeared owing to the supervention of catarrh. Patients with persistent tonsillitis, adenitis, rhinorrhœa or otitis should be isolated for at least 12 weeks from the commencement of the fever. The discharge of patients direct from wards containing others in the acute stage of the disease should be avoided ; isolation for a day or two in a separate apartment is advisable. It is safer to remove those who remain Dick-positive during convalescence from all contact with acute cases. In cold weather the practice of bathing on the very day of discharge is not recommended, as a catarrh may be thus induced. Patients should not pass straight from isolation into the company of children and other susceptible persons.

Individuals in close contact with scarlet fever have at times been found to convey the infection, but a greater source of danger is the convalescent carrier, whose infectivity persists beyond the usually recognised period. The infectivity of such carriers has been known to last for weeks and even months ; there is some evidence that it is intermittent.

The rules originally formulated by the Medical Officers of Schools may be taken as a safe guide in practice, *i.e.* isolation for not less than 6 weeks, provided convalescence is complete and there is no evidence of inflamed throat or of discharge from the nose or ear, no suppurating or recently enlarged glands, and no eczematous patches about the nostrils, mouth or elsewhere. For very mild attacks, 4 weeks in hospital followed by 2 weeks convalescence is sufficient. The quarantine period for contacts is 10 days, provided disinfection was efficiently carried out at the commencement of that period. In institutional and ward outbreaks the contacts should be Dick-tested for susceptibility and throat swabs examined for hæmolytic streptococci. Those who harbour streptococci should be isolated. The susceptibles in ward outbreaks usually receive 5 or 10 c.c. of antitoxin, which establishes a temporary passive immunity.

CURATIVE.—Doubtful cases should be isolated until a definite diagnosis is made. Their premature transfer to a scarlet-fever ward is unjustifiable. Isolation of scarlet fever at home is most successful when a whole floor can be set apart for the patient and attendants, and there are no children of susceptible age in the house. The sick room should be large, light, freely ventilated and adequately warmed, the temperature being maintained at 55° F. to 60° F. Overalls should be worn by attendants, and all articles used by the patient sterilised at once.

The action of the skin is promoted by a daily wash and a tepid sponge every evening during the pyrexial stage. This may be replaced by a daily warm bath when defervescence is complete. The bed coverings should be adequate, but not too heavy. During convalescence, flannel or wool is the proper clothing; chill is by all means to be avoided. During the febrile stage the diet should consist of milk, barley water, or plain water and weak tea. When the temperature falls, beaten-up eggs and farinaceous food may be added and the diet gradually increased, nitrogenous food being allowed early in small amount. Most patients are fit for full diet within a week of the subsidence of the fever. Children, at all events, should be confined to bed for 3 weeks from the onset; by this means chills are avoided, the usual period of onset of nephritis passed, and the throat healed before the patient gets up. When the weather is warm, outdoor exercise may be allowed with advantage in the third or fourth week.

Attention should be paid to the mouth, teeth and gums, since oral sepsis is believed to bring its own train of local complications. The bowels should be regulated with mild aperients.

In all but the mildest cases concentrated scarlatina antitoxin should be given early. The dosage varies from 3000 to 15,000 U.S.A. units according to severity. A unit is the amount which neutralises 50 "skin-test" doses of the standard scarlet fever toxin. Administration is repeated daily in severe cases if necessary. The serum is given intramuscularly. If the intravenous route is chosen, reactions may be very severe, the serum should be diluted, and to guard against anaphylaxis, a preliminary intravenous test injection of $\frac{1}{10}$ c.c. in normal saline is advisable. Preliminary desensitisation is essential in sensitised patients.

Sulphonamide preparations are valuable in the presence of streptococcal complications, but do not influence the toxæmia of the disease.

Osman states that the incidence of nephritis is diminished if sufficient alkali is administered to keep the morning urine alkaline.

Pyrexia, with restlessness, insomnia and delirium, may be controlled by tepid sponging and acetylsalicylic acid or paraldehyde. A cold pack at 60° or 70° F. for 15 or 20 minutes is beneficial when nervous symptoms are pronounced. After the middle of the second week, if albuminuria is present, cold sponging and cold packing should be avoided.

Persistent vomiting may be controlled by the use of diluted or citrated milk or temporary substitution of albumin water. Liquor iodi mitis in doses of 3 or 5 minims is often efficacious. When swallowing is painful the feeds should be small and often repeated. For the local treatment of the throat and nose, gargles are quite ineffective, and sprays have but little cleansing influence. Alkaline carbolic or boric lotions should be applied by gentle syringing or through a douche-can under low pressure. The syringe nozzle, which should be short, is passed into the mouth behind the back teeth, the patient lying on the side of with the head low. It may be necessary to envelop children in a large towel which secures the arms. For very septic and offensive throats a free chlorine lotion should be used every 2 or 3 hours. It is made by putting 200 grains of potassium chlorate in a large dry bottle, pouring on it 40 minims of strong hydrochloric acid, and setting aside, loosely corked, for 10 minutes; a pint of water is then added in 4 or 5 successive portions, shaking well. An equal quantity of water should be added to this solution before use. Great gentleness should be exercised if the nose be syringed; it is generally unnecessary. Ointment should be applied to the nares and upper lip to prevent excoriations.

Secondary tonsillitis is treated on ordinary lines, but care must be taken not to overlook diphtheria. If adenoids and enlarged tonsils delay convalescence, their removal gives good results. Cervical adenitis is treated by smearing glycerine on the neck and applying cotton wool. Poulticing is rarely called for; it appears to precipitate suppuration. Inflamed glands should only be incised when the presence of pus is assured. Care should be taken that the ears are clean. The pain of otitis may be mitigated by syringing with water as hot as can be borne and the application of hot, dry cotton wool, or a rubber hot-water bottle, to the side of the head. By some the instillation of a few drops of glycerin of carbolic acid and the use of fomentations are recommended. Incision of the tympanic membrane is the most efficient method. Discharging ears should be cleansed frequently with hydrogen peroxide and mopped dry with spirit but never plugged. After the fourth week of the fever, removal of adenoids and infected tonsils shortens the duration of discharge. Watch must be kept for mastoid tenderness and œdema.

Scarlatinal rheumatism is usually mild and transitory; salicylates, or acetylsalicylic acid give relief. When joint swellings persist, a mild pyæmic condition is often present, and may be associated with endocarditis. Some advise a cautious trial of intravenous scarlatinal serum in such cases. When the presence of pyæmic arthritis is suspected an exploratory aspiration under strict asepsis may be advisable. This may lead to subsidence.

Scarlatinal nephritis.—The importance of daily examination of the urine and avoidance of chill must be emphasised. No patient with albuminuria should be allowed up. During the acute stage of nephritis the diet should

be limited to milk, fruit juices and barley water. In very acute cases, water only may be given for 24 hours or even longer. The patient should be clothed in flannel and lie in blankets. The bowels should be regulated with salines or compound jalap powder: constipation is often troublesome. Action of the skin should be encouraged by simple diaphoretics and the use of hot bottles, hot packs or an incandescent electric bath, if available. Acetyl-salicylic acid is useful in promoting sweating. Thirty grains each of sodium citrate and bicarbonate should be given three times a day. For uræmia, free purgation and sweating should be induced; venesection is useful in older patients, coupled with saline infusion. Repeated uræmic convulsions call, in addition, for chloral or chloroform. Lumbar puncture may have a good effect. Morphine if used must be given with caution. Blood pressure should be watched and blood urea estimated.

Grave circulatory failure calls for strict recumbency. Strychnine in doses of gr. $\frac{1}{30}$ every 2 or 3 hours is often used, but even more effectual are injections of adrenaline or pituitary (posterior lobe) extract. Diffusible stimulants such as ammonia and ether mixture, and brandy or champagne, are of value. Oxygen inhalation, hot saline by the bowel, or glucose enemata (5 per cent.) are useful accessories.

The most promising treatment for *hæmorrhagic scarlet fever* is blood transfusion, preferably from an immune donor, or free administration of liver extract. Vitamin K or vitamin C may possibly prove of use.

TYPHOID FEVER

Synonyms.—Enteric Fever; Gastric Fever; Typhus Abdominalis.

Definition.—An infectious fever characterised by pyrexia of distinctive type, an eruption of rose spots, enlargement of the spleen, abdominal discomfort and bowel disturbance. Ulceration of the small intestine and enlargement of the mesenteric lymph glands and spleen are distinctive lesions. Typhoid is a septicæmia caused by ingestion of the *Bacillus typhosus* of Eberth, which is absorbed by the lymphoid tissue of the small intestine and carried to all parts of the body; it settles in the agminate glands (Peyer's patches) of the intestine, the mesenteric lymph glands, spleen, liver, gall-bladder and bone-marrow. Those organs which have excretory ducts, *e.g.* the liver and gall-bladder and the kidneys, as well as the intestinal tract, form the chief channels of elimination.

Ætiology.—The *Bacillus typhosus* (*Eberthella typhi*) is a flagellated, rod-shaped organism, about 3μ in length and 0·6 μ in thickness. It is actively motile and easily grown on artificial media. It belongs to the enteric group of organisms, a group which includes also the paratyphoid bacilli (*Salmonella typhi*). It grows best at blood heat and is quickly killed by boiling water, and within 15 minutes by exposure to a temperature of 60° C. (140° F.). It may survive for a considerable time in ice, and also in fresh or salt water. It resists drying, so that typhoid may be propagated by dust or by articles soiled by typhoid excreta. It has been found alive in the mantle-cavity and intestines of oysters, mussels and other shell-fish which have lived in sewage-contaminated water. It grows freely in butter and in milk.

The toxins are mainly intracellular. Inoculation of animals produces a

septicæmia without the intestinal lesions seen in man. Even in the latter the disease at times occurs without producing intestinal ulcers. The serum of patients has a specific agglutinative influence on cultures of the organism, a fact which is made use of in diagnosis, and at certain stages the bacillus can be cultivated from the blood. In man, infection is introduced by the alimentary tract, and is derived, directly or indirectly, from a human source.

Typhoid occurs in all parts of the world, but is most rife in tropical and subtropical countries. In Great Britain it is most prevalent in the months of September, October and November; in other countries the maximum incidence corresponds to the warm season. A hot, dry summer increases the prevalence in the autumn. An epidemic recrudescence is believed to occur every 5 or 7 years. Rather more males than females are attacked, and the greatest susceptibility is between the twentieth and twenty-fourth years. Infants are rarely infected. After the thirtieth year there is a progressive fall in its incidence. It is rare but not unknown in old age.

One attack confers immunity, which usually lasts for life, but second and third attacks have been reported. Where typhoid is endemic a proportion of the community acquires immunity without having passed through a recognisable attack. The supposed racial immunity of certain peoples may in reality be acquired through infection contracted in childhood. Fatigue and overwork are predisposing factors, and no condition predisposes so much as war to typhoid and paratyphoid infections, owing to the aggregation of susceptible subjects under conditions of defective sanitation, fatigue and exhaustion. Prophylactic vaccination has found its greatest triumphs under these conditions.

Propagation from the human source may be indirect or direct. Of indirect causes aerial infection, apart from the influence of wind-borne dust and of flies, is very doubtful. Drinking water supplies contaminated by sewage or the excretions of a carrier are the most common cause of widespread outbreaks. Milk and other articles of food may also act as diffusers of infection. Watercress and green vegetables, eaten uncooked, also spread the disease. Amongst shell-fish, oysters, mussels, cockles and periwinkles are dangerous. Fomites, enema syringes, bedpans, etc., which have been soiled by typhoid excreta undoubtedly act as infective agents. Laboratory workers have been infected by their cultures.

Direct contagion plays but a small part in the production of epidemics, but assumes importance in causing localised outbreaks, infection being conveyed by the fæces, the urine, the vomit, discharges from abscesses and possibly by the sputa. The chief danger arises with mild and unrecognised cases. Strict attention to personal cleanliness and proper disinfection of excreta, soiled linen, feeding utensils, etc., go far to eliminate infection, and prophylactic inoculation is a great safeguard. Of convalescents from typhoid, a small proportion, about 5 per cent., continue to pass bacilli, perhaps intermittently, in the stools for months or years. These are known as intestinal carriers. They may appear to be quite healthy, or may suffer from periodic intestinal disturbance or from symptoms referable to the gall-bladder. Typhoid bacilluria occurs in perhaps 25 per cent. of the cases of typhoid, but is as a rule quite transitory, urinary carriers being much less common but possibly more dangerous than intestinal carriers. Carriers are

particularly dangerous when they happen to be engaged in handling food, milk or water supplies.

The endemic occurrence of typhoid in certain localities is now attributed to the influence of human carriers rather than to the persistence of infection in the soil, although it is an undoubted fact that the typhoid bacillus may persist for a time and even multiply in sewage-infected earth.

Pathology.—The characteristic lesions are in the small intestine. Microscopically, proliferation of the large mononuclear phagocytes of the reticulo-endothelial system is the distinctive reaction. In the early stages the Peyer's patches are hyperæmic and swollen, the swelling attaining its height about the tenth day of the disease. The solitary follicles of the intestine are similarly affected and a diffuse catarrh of both large and small bowel may be present. Necrosis ensues in the inflamed lymphoid masses, and yellowish-brown sloughs are formed, the separation of which occurs during the third and part of the fourth weeks. In some cases, slow resolution may possibly take place without necrosis. The ulcers which result from sloughing of Peyer's patches are ovoid and lie along the long axis of the bowels. Those which arise in the solitary follicles are more circular. The edges of a recent ulcer are undermined, and the floor shows smooth muscular fibres, or sometimes the peritoneal coat. As the sloughs separate, perforation or hæmorrhage may ensue. Immediately above the ileo-cæcal valve irregular sinuous tracts of ulceration may be evident. Ulceration of the large intestine is rare. The ulcers of typhoid heal without contraction. A slaty pigmentation, often punctate, may persist. The time required for healing is a week or ten days. When perforation occurs it is usually in the lower ileum, where ulceration is most intense. It may, however, happen in other situations such as the colon, cæcum, appendix, or, on rare occasions, the jejunum.

The mesenteric lymph glands are hyperæmic and swollen. They rarely suppurate. The spleen is enlarged, softer and redder than normal, and the Malpighian tufts may be prominent. Infarction sometimes occurs, but rupture is rare. Parenchymatous degeneration occurs in the liver, and minute areas of focal necrosis are scattered through its substance. The gall-bladder may become infected and cholecystitis or gall-stones result. Pylephlebitis is a rare complication. Cloudy swelling of the kidneys is the rule, occasionally a parenchymatous nephritis ensues. In chronic urinary carriers inflammation of the renal pelvis or urinary bladder may be found.

The myocardium shows fatty and granular degeneration. Endocarditis is exceptional, but endarteritis may affect the aorta, coronary arteries and peripheral vessels. Hypostatic congestion of the lung bases is the rule with, it may be, distinct broncho-pneumonic consolidation. Lobar pneumonia is uncommon. Gangrene, abscess or infarction of the lungs is rare. Ulceration of the larynx may occur, the ulcers being found in the neighbourhood of the arytenoid cartilages, or at the base of the epiglottis. Necrosis of the cartilages sometimes ensues. Zenker's vitreous degeneration of muscle is particularly marked. It affects the straight muscles of the abdomen, the adductors of the thigh and the diaphragm. Rupture of muscle and hæmorrhage may result. Osteo-periostitis of the tibia, vertebræ and other bones may be due to primary infection with the typhoid bacillus or to secondary invaders. Superficial abscesses, degenerative changes in the central nervous

system or peripheral nerves, and venous thrombosis are also sequels of typhoid infection.

Symptoms and Course.—The period of *incubation* averages from 10 to 14 days, but may be as short as 5 days or as long as 3 weeks. During this period symptoms are generally absent, but ill-defined malaise or, more rarely, gastro-intestinal disturbance may occur.

The *onset* of the fever is generally insidious with chilliness, lassitude, loss of appetite and muscular pains. Symptoms which are particularly suggestive are frontal headache, epistaxis, slight bronchitis and disturbing dreams. The tongue becomes furred, the mouth dry and the bowels loose or constipated. The patient may not take to bed for a day or two. The temperature rises gradually, being a degree or more higher each succeeding night with morning remissions. By the end of the first week the patient's condition is very characteristic. The aspect is heavy and the cheeks are flushed. The lips and mouth are dry, and the dorsum of the tongue covered with a dirty white fur, the tip and edges being raw. The abdomen is slightly tumid, with gurgling in the right iliac fossa. The bowels are generally loose, several liquid motions like pea soup being passed in the 24 hours; sometimes, however, there is constipation. The spleen may be palpable. A characteristic feature is a moderately full but easily compressible pulse, the frequency of which is not increased in proportion to the temperature. The respiration is accelerated. The temperature will by now have attained a maximum of 103° to 105° F., still showing morning remissions of about 1°, and is unstable, reacting quickly to minor disturbances. The urine is high coloured and concentrated, and the skin usually dry. Thirst and headache are the chief complaints.

The rose spots usually make their appearance towards the end of the first week, sometimes on the fifth day, more often between the seventh and twelfth. Each spot is a circular, slightly elevated papule of a pale pink colour from 2 to 4 mm. in diameter, disappearing on pressure. The rash should be sought for on the abdomen, the flanks, the sides of the chest and the back, which should always be scrutinised. The spots appear in successive crops, each one fading in 3 or 4 days, and leaving a transitory brownish stain. Often the eruption is scanty, a few spots only being seen; occasionally it is very profuse, and involves the limbs as well as the trunk. The face usually escapes. Minute sudaminal vesicles occasionally cap some of the spots. The eruptive period lasts from 10 days to 3 weeks. A profuse rash does not necessarily indicate a severe attack. The spots are due to bacterial embolisms.

By the second week the fever (Fig. 2) has reached its fastigium. The temperature maintains its level with slight morning remissions, the headache may abate, but prostration increases and the other symptoms are more severe. The lips become cracked, sordes accumulate on the teeth, the abdomen becomes more distended and diarrhœa is often a marked feature, the stools being liquid, yellow in colour, alkaline and foul. They may be chocolate-coloured or red from admixed blood and small shreds of tissue, or actual sloughs may already be present. The evacuations are not accompanied by colic or tenesmus. The spleen is now larger. The pulse rate will have quickened to a frequency of 112 to 140. It is often dicrotic, and the heart sounds enfeebled. The bases of the lungs may now show signs of hypostatic congestion, and the respiration be more accelerated with slight lividity of the lips and face. Delirium of a muttering character disturbs the sleep, asthenia

is very marked and muscular wasting rapid . The urine may be albuminous. Patients may succumb during this period from toxæmia, or towards the end of the first fortnight from perforation of the bowel or intestinal hæmorrhage.

During the third week improvement should occur, the temperature becoming more remittent in type, the morning reading falling more rapidly than that of the evening. The tongue cleans and appetite begins to return. During the fourth week defervescence may be completed, the temperature usually remaining at a subnormal level for some time. In severe infections, however, the third week is a period of increasing anxiety. The symptoms increase in severity and the patient may pass into the "typhoid state," lying on the back in a semi-stuporose condition. The pulse and heart sounds become more and more enfeebled, the pulmonary congestion increases, the extremities become blue and cold, subsultus tendinum appears, and the evacuations are passed unconsciously. Sometimes there is retention of

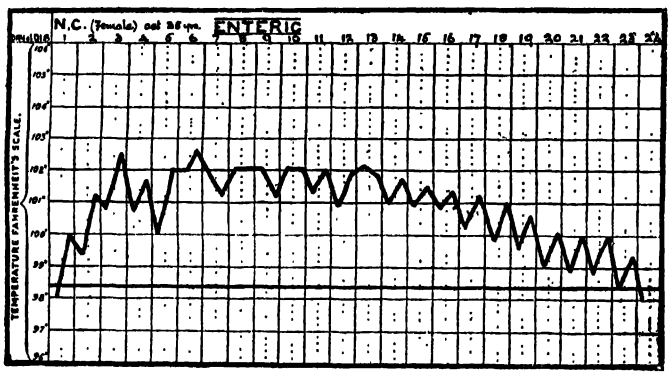

FIG. 2.—Typhoid Fever from the first day. Illustrating gradually rising temperature, a "continued" stage, and a typical lysis.

urine. Extreme abdominal distension may supervene, and the occurrence of perforative peritonitis or of hæmorrhage from the bowel is more than ever to be dreaded. In such severe cases the fever may be prolonged through the fourth and fifth weeks before any signs of defervescence appear. They are not necessarily fatal.

Convalescence after a severe attack is always protracted. The temperature is at first subnormal, and remains in a very unstable state. The heart sounds remain enfeebled, and the pulse is often rather fast or easily quickened by exertion or excitement. The effort of standing and walking is difficult and painful. The appetite, however, is good, and the weight rapidly increases. The aspect gradually becomes less anæmic. Slight peeling of the skin, loss of hair, and ridging or furrowing of the nails is often noticeable. During this period the feet and ankles may show slight œdema, and cutaneous abscesses or localised bone abscesses may occur. Femoral thrombosis sometimes appears; it is the chief complication of early convalescence.

Relapse.—Tendency to relapse is a marked feature, and shows itself in from 5 to 15 per cent. of the cases. The relapse may occur during actual

defervescence, but more commonly develops after an afebrile period of a week or a little longer. The symptoms are a repetition of those of the original attack, but in a mitigated form, the fever reaching its acme in a shorter time, and the whole duration being 10 days or a fortnight. The spleen enlarges again, a new crop of rose spots usually appears, fresh ulceration of the bowel occurs, and blood culture may again prove positive. On occasions, the relapse equals or exceeds the original attack in severity, and may even prove fatal. Spurious relapses are recrudescences of fever during convalescence, of short duration, and unaccompanied by definite symptoms. Their explanation is often obscure.

The fact that typhoid fever may show great variations in its clinical characters, and in the severity and prominence of different symptoms, has led to the description of many special types. Different epidemics may differ much in their salient features.

Variations in onset.—The onset of symptoms may be sudden, sometimes with rigors and vomiting. The temperature rises quickly, and delirium may supervene early. In such cases, death may occur during the second week, or the disease may gradually assume the ordinary type. In exceptional cases, severe bronchitis or pneumonia may mark and mask the onset, and the true nature of the infection may be overlooked. The prominence of meningeal symptoms may lead to confusion with cerebro-spinal fever, and the differential diagnosis only be possible by examination of the cerebro-spinal fluid. If typhoid meningitis is present, lymphocytes or polymorphs predominate, according to the severity of the infection, and the typhoid bacillus grows on culture. More commonly the fluid is under tension but clear; it is sterile and the meningeal symptoms quickly subside after lumbar puncture, to be succeeded by the more typical signs of typhoid fever. Yet another occasional mode of onset is with a primary acute hæmorrhagic nephritis. When acute gastro-intestinal symptoms signalise the invasion, appendicitis or irritant poisoning may be simulated.

The terms *pneumo-typhoid*, *meningo-typhoid* and *nephro-typhoid* have been used to designate some of the above-mentioned types.

Variations in course.—There is an ambulatory form in which febrile disturbance is generally slight, and the patient continues about during the whole or the greater part of the illness. Some such cases end in recovery; but others run a very severe course, the patient taking to bed about the end of the second week with aggravated symptoms, or succumbing to hæmorrhage from the bowel, perforation, acute delirium or circulatory failure. Mild and abortive forms of typhoid also occur in which the fever is insignificant, or, after a well-marked onset, ends in a rapid defervescence between the eighth and fourteenth day. An afebrile form is known, and is said particularly to occur in the enfeebled or those exposed to great hardships.

Variations due to age, pregnancy and other causes.—Typhoid fever is rare in infancy, but becomes more frequent in childhood, and then, generally, the symptoms are mild, the pyrexia of short duration and sometimes of a markedly intermittent or remittent type. Such complications as perforation or hæmorrhage are rare.

In the aged, particularly in those over sixty, typhoid tends to run an unfavourable course, hypostatic pneumonia and circulatory failure being common.

Abortion or premature delivery takes place in from 50 to 70 per cent. of pregnant women who contract typhoid. The fœtus is dead or, if born alive, usually succumbs to an acute typhoid septicæmia. The prognosis as regards the mother is not especially influenced.

In malarial patients the onset of typhoid may be sudden, with a typical rigor; but the severe symptoms proper to typhoid develop later. On the other hand, subtertian malaria may closely simulate typhoid in its commencement.

Chronic alcoholism exerts a very unfavourable influence. Pre-existing pulmonary tuberculosis is apt to advance rapidly during convalescence from the fever. In diabetes typhoid often runs a mild course.

Special Symptoms and Complications.—*Digestive system.*—Suppurative parotitis is attributed to duct infection, and occasionally leads to cellulitis. Attention to the cleansing of the mouth goes far to prevent it. Ulcers sometimes appear on the pillars of the fauces and the pharyngeal wall (Duguet's ulcerations). Diarrhœa is not a constant feature, some patients being constipated throughout the disease. The diarrhœa often disappears after a few days' hospital treatment, but in bad infections it may be severe and persistent.

Meteorism with a distended, tense, tympanitic abdomen signifies a virulent infection. It may or may not be accompanied by severe diarrhœa, and is often a harbinger of hæmorrhage or perforation.

Intestinal hæmorrhage occurs in about 7 per cent. of all cases, and is serious. It is most common at the time when the sloughs are separating, *i.e.* at the end of the second or beginning of the third week. The hæmorrhage may be slight, but more often is profuse. The evacuated blood is bright red in colour, unless it has been retained in the bowel. The signs of a severe hæmorrhage are a sharp fall in the temperature, a sensation of faintness, increased frequency of the pulse and, it may be, a transient rise in blood pressure with disappearance of dicrotism. The spleen may shrink rapidly. Sometimes the hæmorrhage is fatal before any blood is voided. There is a hæmorrhagic form of typhoid in which melæna may be an early sign, associated with petechiæ or bruises in the skin and hæmaturia. The outlook, then, is very grave.

Perforation of the bowel causes one out of every 3 or 4 deaths. Its incidence is something under 5 per cent. It is commonest towards the end of the third week, especially in cases characterised by severe diarrhœa or by meteorism. Its onset may be preceded by intestinal hæmorrhage. The perforation generally lies within the last 12 inches of the ileum, but may occur elsewhere. Shivering, with sharp pain in the right iliac fossa, is usually the first sign. Localised tenderness, localised rigidity and local immobility of the abdominal wall accompany the pain. The temperature may show a sudden drop to a subnormal followed by a rise; but sometimes no variation is detected. Both pulse and respiration rates are usually increased, and the former should be watched carefully. Obliteration of the liver dullness may occur; this sign is especially valuable when occurring in a rigid and retracted belly. Another sign is the occasional onset of irritability of the bladder. More reliance should be based on the local than on the general symptoms in making the diagnosis. After the first shock the patient may react and show deceptive signs of improvement, but before

many hours the signs of spreading peritonitis will assert themselves. Unless dealt with surgically with the utmost promptness perforation is almost invariably fatal. A polynuclear leucocytosis generally accompanies perforation, but is inconstant and not of great diagnostic value.

Other causes of abdominal pain in typhoid fever are acute cholecystitis or perforation of the gall-bladder, suppurative cholangitis, portal pyæmia, suppurating mesenteric glands, appendicitis and splenic infarction, but none of these is common. Thrombosis of the iliac veins may also cause abdominal pain and tenderness, but a clue to this condition may often be found by examining the veins of the lower limbs and by looking for slight œdema of the leg or foot. Gall-stones are a recognised sequel of typhoid infection, and may contain typhoid bacilli.

Respiratory system.—A mild bronchitis is present in most cases. In severe infections, hypostatic congestion of the lung bases occurs. Lobar pneumonia may supervene in the third or fourth weeks of the disease. Although typhoid bacilli may occur in the sputum, and be found in the lung, pneumococci are also present; the condition may be overlooked, as cough is often slight and rusty sputa absent. Embolic and pyæmic processes in the lungs during typhoid may give rise to abscess, gangrene and pneumothorax. Intra-pulmonary thrombosis, with infarction, is a very rare event.

Ulceration of the larynx is not infrequent in severe cases. It may be latent or give rise to huskiness of the voice, stridor and toneless cough. There may be pain on deglutition and laryngeal tenderness. The slighter symptoms may abate, but sometimes the process terminates in necrosis of cartilage and œdema or stenosis of the larynx.

Blood and circulatory system.—A slight polynuclear leucocytosis is sometimes seen in the first week of infection. More characteristic is anæmia associated with leucopenia, and a relative increase in the lymphocytes and large mononuclear cells. At the same time the eosinophils disappear to reappear with convalescence. The appearance of a polynuclear leucocytosis indicates the onset of inflammatory complications

Circulatory failure is a feature of severe attacks. The pulse rate, usually but moderately accelerated in typhoid, rises to 120 or more, dicrotism disappears, the cardiac sounds weaken, and the blood pressure falls. Acute collapse, with sudden drop of temperature, coldness of the skin, cyanosis and feeble or irregular pulse, may ensue. The collapse may be recovered from, but its occurrence is ominous.

Femoral thrombosis is apt to appear during early convalescence. It is usually left-sided, and sometimes appears to commence lower down in the veins of the popliteal space or calf or in the internal saphenous trunk. The symptoms are pain and tenderness at the site of the thrombosis, fever and swelling of the limb, usually moderate in degree. The affected vein may often be felt as a tender cord. In a few weeks the thrombus is absorbed, and the circulation re-established, but sometimes permanent obstruction and œdema result. The clot, if dislodged, may cause pulmonary embolism.

Arteritis, leading to occlusion, is an uncommon complication. The vessels affected are those of the lower limbs, sometimes those of the upper extremities, neck or brain.

Urinary system.—Febrile albuminuria is often present, but is transitory. Typhoid bacilluria occurs in some cases, the urine presenting a slightly

turbid, opalescent appearance; but a similar appearance may be due to the colon bacillus. Symptoms of pyelitis, pyelo-nephritis or cystitis may supervene. Urinary carriers continue to discharge typhoid bacilli for long periods. Acute nephritis is uncommon, but may occur either at the commencement or height of the disease. Retention of the urine may supervene during typhoid, but suppression is rare. During the fever the excretion of urea and of uric acid is increased, but the chlorides are diminished. A moderate oliguria is the rule. A considerable reduction, in spite of free fluid intake, is evidence of a severe attack. Polyuria occurs at the onset of convalescence, and is of good omen.

Generative system.—Orchitis and prostatitis have been observed. In females vulvitis and also mastitis may occur.

Nervous system.—Meningeal symptoms at the onset have already been mentioned. Delirium is often present and is usually of a quiet type. Drinkers may develop delirium tremens. Convulsions are rare. They may occur at the onset, or when occurring later may be due to cerebral thrombosis, encephalitis, or meningitis. Multiple neuritis or neuritis of such nerves as the ulnar may supervene, in the latter case often due to pressure. Acute tenderness of the toes during convalescence is also attributed to neuritis. During the course of the fever hemiplegia or aphasia may supervene. Sometimes there are signs of sclerosis of the lateral columns of the cord, the knee-jerks being increased, and an extensor plantar reflex present.

Mental disturbance is occasionally a sequel, taking the form of mania, melancholia or dementia. For many months after a severe attack the patient may remain in a fatuous condition but ultimately recover.

As regards the special senses, temporary deafness is often noticeable during the fever, and sometimes suppurative otitis. Double optic neuritis is a rare complication and may lead to blindness.

Osseous and muscular systems.—During convalescence localised osteo-periostitis of the tibia, sometimes of the femur, ribs or other bones may appear. It may terminate in suppuration with limited necrosis. The inflammation is chronic and relapsing. Typhoid bacilli may persist in the pus for long periods. A painful inflammatory affection of the ligaments and vertebral periosteum is the basis of the "typhoid spine." The lumbar and sacral regions are chiefly involved, with stiffness and pain on movement. The condition is chronic, but the ultimate outlook is said to be good. Arthritis of large joints is a rare occurrence; it may lead to dislocation of the hip.

Rupture of the rectus abdominis, sometimes of the adductors or other muscles, may take place. It is accompanied by local hæmorrhage. The resulting fluctuating and discoloured swelling may clear up or go on to suppuration.

Cutaneous system.—Abscesses and boils may prove troublesome. Lineæ atrophicæ may form in the skin of the abdomen and thighs. In severe cases pressure sores may appear on the sacrum, the heels or other pressure points. These bed-sores are a source of danger from septicæmia or pyæmia.

Diagnosis.—It is unnecessary to recapitulate all the symptoms already described as characteristic. Of the symptoms of onset, headache, slight epistaxis, disturbed sleep, a mild degree of bronchitis, abdominal uneasiness and some disturbance of the action of the bowels are very suggestive. Gradual daily increase in the pyrexia and its maintenance after the lapse of a week at a

steady level of 103° or 104° F., with slight morning remissions, is important. Relative slowness of the pulse and the presence of dicrotism are additional diagnostic points. The dry furred tongue, slightly tumid abdomen, moderately enlarged spleen and the appearance of rose spots are confirmatory.

Special Diagnostic Methods.—1. *Blood examination.*—Culture is particularly valuable in the first week before the agglutinative reaction has appeared or the rose spots are evident, but is also applicable during the second and third weeks and in relapse. Ten to 20 c.c. of blood drawn aseptically from a vein at the bend of the elbow are allowed to run directly into plenty of broth or peptone solution or, better, into a medium which contains filtered bile or bile salts. At the same time a blood count should show a characteristic leucopenia.

2. *Cultures from bone-marrow* obtained by sternal puncture are said to be more often and more persistently positive than blood cultures.

3. *Cultures from the stools.*—Owing to the presence of other intestinal bacteria this is not always an easy process, but by improved methods bacilli have occasionally been found during the incubation stage and in over 50 per cent. of the cases examined in the first week, a percentage increased to 70 or 80 in the third week. For methods, works on bacteriology should be consulted. Stool culture is also of value for the detection of intestinal carriers, and for determining whether a convalescent is fit to mix with other members of the community. The discharge of bacilli often being intermittent, more than one examination is necessary.

4. *Cultures from the urine.*—The typhoid bacillus hardly ever appears in the urine before the tenth day, and as a rule not before the fifteenth. The infected urine is generally opalescent and slightly albuminous. Cultures are made without difficulty and are useful not only for diagnosis but also for the detection of urinary carriers.

5. *Agglutination tests.*—Towards the end of the first week of the disease the blood serum becomes capable of agglutinating the typhoid bacillus. This power usually reaches its maximum about the eighteenth or twenty-first day. Blood is obtained from the lobe of the ear or a vein. The serum which separates is mixed in various dilutions with a young (18 to 24 hours) broth or agar culture of the typhoid bacillus and a hanging-drop preparation made. Controls are indispensable. Agglutination of 1 in 50 with a time limit of one hour is usually taken as the positive standard, but some prefer a titre of 1 : 100 especially if the macroscopic technique is adopted. The bacilli first lose their motility and then aggregate into small clumps. The macroscopic method of applying the test allows the bacilli to sediment in flakes at the bottom of small tubes; Dreyer's method in which standardised dead cultures are used is the best; it is quantitative. Normal blood serum does not show an agglutinating power greater than 1 in 10 or 1 in 20. Rising titres are highly diagnostic.

Corresponding to three types (H, O and Vi) of receptor or antigen in the infecting organism three kinds of agglutinin are found in the blood. The H antigen is specific and distinguishes the organism present. This antigen is present alone in Dreyer's formolised suspension. The O antigen, on the other hand, is common to the enteric group. The presence of its corresponding agglutinin in a patient's serum is proof only of infection by a member of the group; it does not identify it. The Vi antigen rarely occurs alone.

T.A.B. vaccine, in consequence of its mode of preparation, evokes H agglutinins chiefly, and these may persist for some years. The appearance of O agglutinins in an inoculated person shows an enteric infection. Blood culture or examination of the excreta may reveal its identity. A rising titre of H agglutination for a particular organism may also do this, but it is known that other, quite different, infections may also raise the H titre (*anamnestic reaction*).

6. *The atropine test of Marris.*—In typhoid and paratyphoid fevers atropine has but little power of accelerating the pulse. Marris's test is based on this fact, but is little used.

7. *The Diazo reaction.*—A saturated solution of sulphanilic acid in 1 in 20 hydrochloric acid and a fresh half per cent. solution of sodium nitrite are required. Equal quantities of urine and sulphanilic solution are mixed in a test-tube and a couple of drops of the nitrite added. By shaking, a froth is induced and ammonia is allowed to trickle down the side of the tube. If the froth becomes rose pink and the liquid turns crimson, the test is positive. The reaction may sometimes be obtained as early as the fourth day, and persists during the height of the fever. Unfortunately it also occurs in measles, typhus fever, scarlet fever, pneumonia, tuberculosis and erysipelas.

Differential Diagnosis.—Prominence of respiratory or bowel symptoms in typhoid fever may lead to the infection being overlooked. Conversely a deep-seated or apical *pneumonia* or, in children, *broncho-pneumonia* with intestinal disturbance, may simulate typhoid. Careful and repeated physical examination, blood culture and agglutinative reactions will lead to a correct diagnosis. When typhoid is prevalent, caution is necessary in arriving at a diagnosis of primary bronchitis, pneumonia, broncho-pneumonia, and, especially in children, gastro-enteritis.

Differentiation from *acute miliary tuberculosis*, from *tuberculous meningitis* and from *tuberculous peritonitis* is often difficult. Acute miliary tuberculosis may simulate typhoid in its insidious onset with malaise and headache, its rising temperature with morning remissions, its comparatively slow pulse, its bronchitis, and perhaps some enlargement of the spleen. But the temperature tends to be more irregular, sweats are present, the dyspnœa and cyanosis are suggestive, and signs of pleurisy may develop. There are no rose spots, and agglutinative tests and blood culture give negative results (tubercle bacilli are rarely found). Tuberculous meningitis is differentiated by such symptoms as vomiting, convulsions, the persistence of headache after the first week, or when delirium is established. A pulse hardly raised above the normal rate, stiffness and retraction of the neck, the presence of Kernig's sign and of retraction of the abdomen or the onset of ocular paralysis are very significant. The irritability and curled-up decubitus of meningitis contrasts with the apathy and dorsal decubitus of typhoid. Lumbar puncture will clinch the diagnosis; in tuberculous meningitis lymphocytes are in excess in the cerebro-spinal fluid, and sometimes tubercle bacilli may be demonstrated. The question of meningo-typhoid has already been discussed. Tuberculous peritonitis may resemble mild typhoid fever. The presence of tuberculous masses in the abdomen or the development of peritoneal or pleural effusions is significant. In cases with indefinite symptoms and no signs of tubercle elsewhere, negative blood culture and agglutination tests afford assistance.

Suppurative and pyæmic conditions may give rise to fever and constitutional disturbance bearing some resemblance to typhoid. Among these must be mentioned appendicitis and the intraperitoneal abscesses which may result from it, perinephric abscess, cholecystitis, pelvic, or puerperal infections, infective endocarditis and deep-seated osteomyelitis. The diagnosis is made by careful attention to the history of onset and course, thorough and complete physical examination, and the frequent presence of a pronounced polynuclear leucocytosis. Profuse sweats and rigors are more likely to occur, and the temperature chart is more irregular. The blood serum fails to agglutinate typhoid bacilli, nor can they be obtained by blood culture, which may, however, reveal the presence of other organisms.

Typhoid fever in its early stages is often mistaken for *influenza*, but in the latter the onset is generally sudden and the early symptoms are more severe. The temperature reaches its maximum much sooner. The pains in the limbs and the backache are more intense, and the headache, which has a neuralgic character, is frequently supra-orbital. Catarrh of the conjunctivæ and nose may be present, and perspirations are often marked. Defervescence usually takes place within a few days. A sharp drop of temperature after 2 or 3 days with a sudden rebound 12 or 24 hours later is very characteristic. If a supposed influenzal fever persist without definite cause, typhoid should be suspected.

A mild case of *typhus* may bear a close resemblance to typhoid, and severe typhoid with grave toxæmia, stupor and a profuse eruption may be mistaken for typhus. Points in favour of the disease being typhoid are a slower onset, the later appearance of the eruption, which is never petechial, and the presence of bowel symptoms. Typhus, on the other hand, has a sudden onset with high fever which sooner attains its maximum and does not show morning remissions. Conjunctival injection, contracted pupils and a drunken expression are the rule. The rash appears on the fourth day, becomes petechial and is accompanied by subcuticular mottling. Prostration is marked and there is a greater tendency to delirium and stupor. Crisis occurs about the fourteenth day. The Weil-Felix reaction is present, but agglutination tests for typhoid are negative except in inoculated persons (p. 88).

Undulant (Malta or Mediterranean) fever is distinguished from typhoid by its relapsing character, the prominence of arthritic pains and joint swellings, and the fact that the blood agglutinates the *Micrococcus melitensis*, which organism can also be recovered by blood culture. Closely allied to this is the fever produced by *B. abortus* of cows.

When *malarial fever* assumes the continuous type, which is likely to occur with the malignant infections, the diagnosis turns on known exposure to malaria, sudden onset, the detection of malarial parasites in the blood and the reaction to quinine. Malaria and typhoid fever, however, may coexist.

The fever of *secondary syphilis* is sometimes sufficiently severe to suggest typhoid, especially when accompanied by headache, malaise and muscular pains. Diagnosis depends on the history or detection of a primary lesion, the possible presence of a secondary roseolar eruption and on laboratory tests. Deep-seated malignant disease may also cause prolonged fever.

Amongst other diseases at times confounded with typhoid must be

mentioned psittacosis, kala-azar, glanders, trichinosis, fever due to *Ascaris lumbricoides*, scarlet fever in which pyrexia is prolonged, that type of glandular fever in which the glandular swelling is delayed, and especially fevers of the Salmonella group, *i.e.* paratyphoid A, B or C.

Prognosis.—Taking all ages, the death-rate varies from 5 to 25 per cent. It is higher in some epidemics than in others. The average hospital death-rate in London is 17 per cent. or a little less. Age has a decided influence on the mortality, which is least in children from 5 to 10, after which there is a steady increase with advancing years. Infants are believed to stand the infection very badly. Obesity, alcoholism, privation and fatigue are adverse factors. The influence of pregnancy has already been discussed. Indications of a grave attack are a pulse rate of 130 or 140, cyanosis with signs of failing circulation and hypostatic congestion of the lungs, marked delirium and subsultus or actual coma, persistent diarrhœa, tympanites, incontinence of urine and fæces. A temperature of 103° or 104° F. is not necessarily unfavourable unless it is sustained beyond the usual period or accompanied by signs of heart failure. Delayed appearance of the agglutinative reaction in some instances indicates a severe attack.

Of the complications, next to toxæmic circulatory failure, perforation is the most grave. Without operation it is almost invariably fatal. With operation the recovery rate is difficult to fix—some surgeons claim success in over 30 per cent., but the intervention must be immediate. The average recovery rate is very much lower. Hæmorrhage from the bowel is undoubtedly serious, especially if repeated. Such complications as meningitis, lobar pneumonia and acute nephritis are dangerous but fortunately not very common.

Sudden death sometimes occurs, either at the height of the fever or in convalescence. It may be caused by intense toxæmia and circulatory failure, cardiac or pulmonary thrombosis or pulmonary embolism. Rarely no definite cause can be assigned.

Treatment.—PROPHYLACTIC.—Patients should be isolated. Adequate disinfection of the fæces, the urine, the pus from abscesses, the vomit and the sputa is necessary. Blood discharged from the nose or bowel should also be looked upon as infectious. Equally essential is the disinfection of the bedclothes and personal linen of the patient, the feeding utensils, thermometer, bed-pan, urinal, spittoon and enema syringe. The stools and urine should be mixed with an excess of some such disinfectant as carbolic acid or corrosive sublimate, and allowed to stand for several hours before being thrown down a drain. The sputa should be received in small cloths which can be burned, or expectorated into a disinfectant solution. The clothing and bedclothes of the patient should be soaked in a 1 in 20 solution of carbolic acid before being sent to a laundry.

Nurses in attendance should submit to prophylactic inoculation and take special precautions for their own safety. Overalls will obviate soiling of the clothes. If the bath treatment is adopted, rubber aprons which can be carbolised are advisable. Rubber gloves may be worn when giving enemas or touching bed-pans and urinals, but always it should be realised that typhoid acquired by contact is a disease conveyed by unclean hands, and the danger may be obviated by washing with plenty of soap and water after touching the patient or anything which has been in contact with him. Everything

leaving the patient or used by him must be sterilised at once. Feeding utensils should be boiled after use.

In most cases the bacilli disappear from the excreta in convalescence, only persisting for a few weeks, but bacteriological examination several times repeated affords the only proof of safety. About 5 per cent. of those attacked become carriers. In most the carrier state is temporary and an arbitrary period of 3 months is allowed before the condition is deemed chronic. Intestinal carriers are more common than urinary carriers. In both the discharge of bacilli may be intermittent. Symptoms referable to the gall-bladder and periodic bowel disturbance occur in some intestinal carriers, and urinary carriers in like manner may suffer from kidney trouble or cystitis. Carriers do not necessarily give a positive Widal reaction.

Carriers are often responsible for the endemic persistence of typhoid in certain houses or localities and are particularly dangerous when employed in the preparation of food or in dairy work or in connection with water supplies. They should be prohibited from following these occupations. Since they may spread infection by contaminating their own hands during defæcation or micturition they should be scrupulous in washing after attending to the calls of nature and have towels reserved for their own use. Their soiled bed and body linen must be disinfected. Medical treatment by the use of intestinal and urinary antiseptics, surgical by excision of the gall-bladder, and treatment by autogenous vaccines have up to now alike failed to solve the problem of the chronic carrier. Preventive inoculation of contacts is the most effectual method of limiting their danger and is adopted in special circumstances. Some carriers give no history of an attack of typhoid and may themselves ultimately develop an attack of the fever or suffer from typhoid septicæmia after operations on the gall-bladder or kidney.

A pure water supply and an efficient system of drainage are important factors in the prevention of typhoid epidemics. When the disease is prevalent, drinking water and milk should always be boiled, and travellers in localities where it is endemic should adopt similar precautions. Uncooked vegetables and, in particular, radishes, salads, cress, tomatoes, cucumbers, strawberries and other fruits are liable to contamination. Oysters and other shell-fish should be avoided unless their source is known to be above suspicion. The disease has been contracted by bathing in sewage-contaminated water.

Prophylactic vaccination.—Immunity can be artificially induced by vaccination with typhoid vaccine. There are several methods of preparation of vaccine, one of which is to heat a 48-hour broth culture to 58° C., and complete the sterilisation by the addition of 0·5 per cent. lysol. Exposure to higher temperatures diminishes the potency of the vaccine. The number of bacteria in the first dose is 500 million, a double dose is given 10 days later and repeated 10 days later still. The injection is made subcutaneously and preferably not after a heavy meal or exposure to fatigue. A mild local reaction and sometimes constitutional symptoms may occur a few hours after injection, hence the patient should rest. If the patient is already infected the reaction may be more severe. The duration of the immunity conferred is said to average 1 to 2 years and to be proportional to the dosage employed. An individual inoculated at the beginning of the incubation

period of typhoid has a good chance of escaping the fever, but in rare cases the inoculation appears to aggravate its course. For army purposes, triple or quadruple vaccines of the organisms of typhoid and paratyphoid are largely employed.

CURATIVE.—In the absence of efficient sera or vaccines there is at present no specific. Skilful nursing and a suitable diet are of the first importance. The room should be kept at a temperature of 60° F., and the bed narrow and of a convenient height. A hair or rubber mattress is covered with two folds of blanket and a waterproof sheet over which is placed a sheet, and under the hips a draw sheet. A water-bed is unnecessary. A sheet and coverlet with a blanket over the feet are usually sufficient covering. Night and morning the patient should be sponged with tepid water, and parts exposed to pressure should be rubbed with surgical spirit, and dusting-powder applied. Rucking of bedclothes should be avoided. The urinal and bed-pan should be used in the recumbent position, and the buttocks sponged, dried and powdered after each motion. The mouth should be cleansed after each meal. From time to time it may be advisable to move the patient from the dorsal position to avoid hypostatic congestion of the lung bases. Stools and urine should always be reserved for inspection by the medical attendant, who should never neglect daily examination of the abdomen, and should also satisfy himself that the patient, especially if restless, had not retention of urine. The temperature pulse and respirations should be charted 4-hourly, and more frequently should complications be suspected.

Milk is the most suitable diet for patients in the acute stages. It should be given in measured quantities at 2- or 3-hourly intervals, the patient not being disturbed at night should he be sleeping. Three pints a day is, despite theoretical considerations, quite sufficient. The milk should be diluted with barley water or lime water, and plenty of plain cold water or fruit juice allowed between the feeds. Tea may be allowed or lemonade made with dilute hydrochloric acid and syrup of lemons. Should intestinal discomfort occur or curds appear in the motions the milk may be citrated or whey substituted. Beef-tea and meat extracts are to be avoided in diarrhœa or hæmorrhage. Carbohydrate can be added to the diet in the form of glucose or lactose. Junket and also apple-sauce are useful.

When the temperature has been normal for 3 days, cautious additions may be made, beginning with thin custard or grated bread-crumbs and milk, and then adding a small quantity of boiled or steamed fish, thin bread and butter, and so on.

High calorie diets are based on the belief that during the fever a daily intake of 4000 to 5000 calories is necessary to maintain nitrogenous equilibrium. Even in patients who are amenable this diet is prone to produce digestive upsets and meteorism, but mild cases can take a more liberal diet during the acute stage, *i.e.* milk puddings, custards, eggs, vegetable or meat soups strained and thickened with arrowroot or flour, finely minced lean meat, bread crumbs and mashed potato. Such feeding is said actually to diminish the tendency to perforation and hæmorrhage, and to hasten convalescence. It is not suitable in severe attacks or for patients with profound toxæmia and deficient digestive secretions. Alcohol is rarely necessary, but it is unwise suddenly to deprive alcoholic patients of all stimulants.

The antipyretic treatment of typhoid assumes that pyrexia itself is harmful. The cold bath is most efficient. Best suited to hot climates, it has never gained a great vogue in England. Whenever the temperature rises above 102°·3 F., the patient is lifted into a bath at 65° F. and immersed for 15 minutes, shivering being disregarded. The limbs and trunk are rubbed whilst in the bath. The patient is then removed, laid on a blanket, dried and lightly covered. A little alcohol is given immediately before or after the bath. Immersion is repeated every 3 hours unless the temperature remains below the point mentioned. Contra-indications are hæmorrhage from the bowel, severe abdominal pain, venous thrombosis or great prostration. The method needs good attendants, and can hardly be applied in private, but it is said to reduce the case mortality by a half or even two-thirds. In place of the bath, tepid, cold or ice sponging may be adopted when the temperature is high, or the cold pack used, especially when nervous symptoms are pronounced. The ice cradle is another useful means of refrigeration; the patient is covered with a sheet, and a cradle, in which small rubber bags of ice are suspended, is placed over the body, the whole being covered with a thin blanket. The cradle may remain in position indefinitely, the effect on the temperature being carefully watched.

Some advocate daily mild purges, such as calomel or drachm doses of castor oil, in the early days of infection, and claim that intestinal fermentation can be checked by the administration of various intestinal antiseptics.

Constipation should be met by a simple enema every second day. In defervescence liquid paraffin may be substituted. *Diarrhœa*, if accompanied by curds, calls for reduction of the milk. A starch and opium enema is useful, or 10 grains of Dover's powder by the mouth. In *hæmorrhage from the bowel* the most absolute rest is essential. Food should be reduced to a minimum or withheld for 12 or 24 hours. No stimulants or beef-tea are permissible. Ten minims of laudanum or a hypodermic injection of ¼ grain of morphine should be given, and an ice-bag applied to the right iliac region. A watch should be kept for signs of perforation. Intravenous saline infusion, or, better, transfusion of blood, may be necessary in severe cases. The injection of a solution containing 1 grain of calcium chloride in 10 minims of water into the gluteal region is worth a trial. *Perforation of the bowel* calls for immediate operation. *Meteorism* may be controlled by reducing the diet, administering enemata of hot water, and inserting the rectal tube. A turpentine stupe or ice-poultice may be applied to the abdomen. Turpentine by the mouth or by enema, and oil of cinnamon are useful. For *delirium*, *sleeplessness* and *headache*, the reduction of temperature by sponging or cradling and the administration of 10 or 15 grains of Dover's powder should be tried. Sometimes soluble barbitone (medinal) and aspirin are effectual. *Circulatory failure* is combated by strychnine or strychnine and adrenaline hypodermically, or by injection of nikethamide (coramine) or leptazol (cardiazol). Strophanthus and digitalis are of doubtful value. Alcohol is strongly advocated by some physicians. The supervention of *femoral thrombosis* calls for strict immobility of the limb. The intravenous injection of 5 or 10 ounces of a sterile 0·5 per cent. sodium citrate solution relieves the pain, and is said to arrest the progress of the thrombosis. *Bacilluria* and *cystitis* are treated by hexamine in 10-grain doses, 3 or 4 times a day; if persistent, sulphonamides may be effective. Of the suppurative and septic

complications, *periostitis* may be influenced by rest, local applications and typhoid vaccine, but suppuration calls for surgical intervention. *Parotitis* usually comes to incision. *Cholecystitis* may subside, and should be given a chance to do so, but if it persists operation becomes necessary. Crops of *boils* call for local treatment, and the appropriate vaccine or toxoid should the organism be identified. The intramuscular injection of colloidal manganese is useful in such conditions. The infectivity of purulent discharges should be remembered.

PARATYPHOID FEVER

Ætiology.—Paratyphoid fevers are, like true typhoid, ubiquitous in their distribution, but the prevailing type is different in different countries and in different climates. The infecting organisms belong to the group *Salmonella typhi*. Paratyphoid A is prevalent in India and other tropical countries. The experience of the War of 1914–1918 led to the suspicion that it may have been endemic, although unrecognised, in the Mediterranean area, and perhaps also in France, Flanders and Germany. In European countries, however, paratyphoid B is the more common type. Paratyphoid C occurs in the Balkans, and possibly there are also other varieties. *Bacillus paratyphosus* A and *Bacillus paratyphosus* B are organisms which under natural conditions only attack man, but it is stated that the intestines of domestic animals may contain the bacilli. *B. paratyphosus* C is by some considered identical with *B. suipestifer*, the hog-cholera bacillus.

The greatest incidence of paratyphoid is in the summer and early autumn, but it may occur at other seasons of the year. It is more prevalent in hot countries, and all ages are susceptible. In ordinary circumstances it affects both sexes equally.

The primary source is a patient suffering from an attack, or a carrier of the bacillus. Contagion, as with typhoid, may be direct or indirect through food, especially cream, drinking water, fomites, etc. The infection of water supplies is not so well established as in the case of true typhoid. The fact that infected meat, particularly pork, may induce symptoms resembling paratyphoid fever should be borne in mind.

Symptoms.—The *clinical manifestations* of paratyphoid infections are practically indistinguishable from those of typhoid fever, but the belief is generally held that paratyphoid differs from typhoid in its milder character and shorter course. This is on the whole correct, but marked exceptions occur. Occasionally paratyphoid infection is said to produce an illness which resembles acute irritant poisoning, or so-called ptomaine poisoning. But such infections are more likely to be caused by *B. aertrycke*, which in its agglutination reactions closely resembles *B. paratyphosus* B. In true paratyphoid the subsequent course is clinically unmistakable.

The septicæmic stage of paratyphoid is of short duration, rarely lasting more than a week, hence blood cultures for diagnostic purposes should be taken as soon after the third day as possible. The distribution of the infecting organisms in the body is similar to that of typhoid, and they are discharged in the fæces, the urine, the bronchial secretions, and the pus of suppurating foci. Residual foci of infection are said to be more common in paratyphoid than in typhoid infections.

The *incubation* period varies from 9 to 15 days, but may be shorter.

The *onset* is more often insidious than sudden, the invasive symptoms resembling those of typhoid, but a sudden onset is believed to be more common than in the latter disease. Shivering and vomiting are not infrequent symptoms of such invasion. Sometimes gastro-intestinal symptoms are for a time very prominent, and are particularly misleading in childhood. As with typhoid, influenza, appendicitis, meningitis, or pneumonia may at first be simulated. Sometimes the disease declares itself after several weeks of premonitory diarrhœa, or it may closely resemble dysentery.

The fever attains its maximum sooner than in typhoid, and may be at its height by the third or fourth day, by which time, if not before, the patient will have taken to bed with symptoms suggesting typhoid of a week's duration. The head aches, the patient is apathetic, and the spleen is generally palpable and sometimes tender. The liver may be slightly enlarged, and the gall-bladder tender if cholecystitis be present. The abdomen is generally somewhat tumid, but marked distension is uncommon. Diarrhœa may occur at the onset, but constipation is more common. Sweating is often a more pronounced feature than in typhoid. Rose spots are present in unusual profusion in some cases. They usually appear towards the end of the first week. In size, too, they often appear larger than those seen in ordinary typhoid infection, and the rash may continue to come out after the temperature has fallen. Pulmonary complications are mild, but bronchitis and broncho-pneumonia may occur. In the more severe cases, the heart may show signs of dilatation. It is exceptional for the patient to pass into the "typhoid state." The fever has a shorter duration and shows greater variations than in typhoid. Within a fortnight, sometimes sooner, it has generally fallen by rapid lysis to normal. The slow pulse and low blood pressure of typhoid are also seen in the paratyphoid variety. Relapse is said to be just as frequent.

Complications.—Intestinal hæmorrhage is much less common and less severe than in true typhoid. Perforation is rare. Thrombosis of the femoral or saphenous veins or their radicles is not uncommon, and broncho-pneumonia or pleural effusions may occur. Cholecystitis and catarrhal jaundice may be due to paratyphoid organisms, as also bacilluria, cystitis, pyelitis and even pyelonephritis. Orchitis is an occasional complication, and is believed to spread from the urinary tract. Other complications, which have mostly been observed in army practice, are laryngeal ulceration, parotitis, periostitis, sometimes suppurative, peritonitis without perforation of the bowel, and pylephlebitis, attributed to lesions of the appendix.

Diagnosis.—For the differentiation of paratyphoid from typhoid infections and of the varieties of paratyphoid from each other, recourse must be had to bacteriological methods, *i.e.* to blood culture, agglutinative reactions and cultures from the stools and from the urine. Of these methods, blood culture in the early stages is the most satisfactory. If agglutination occur in high dilutions with one of the paratyphoid organisms and little or not at all with the others and the organism of typhoid, the nature of the infection is evident; but in other cases the examination has to be repeated at short intervals and the results compared. A rising agglutination for one organism indicates it as the causal agent. Some infections with paratyphoid C fail to produce agglutinins in the patient's serum.

Prognosis.—The prognosis in paratyphoid infections is better than in those due to the *B. typhosus*, the proportion of severe infections being much smaller, and the mortality much lower. The causes of death are chiefly hæmorrhage, perforation, lung inflammations and toxæmia.

As regards differential diagnosis, prophylaxis and treatment, what has already been said with regard to typhoid applies.

CHARLES R. BOX.

DIPHTHERIA

Definitions.—A disease caused by the Klebs-Loeffler bacillus (*Corynebacterium diphtheriæ*), characterised by a membranous exudate at the site of infection and distinctive sequels of toxæmic origin, the chief being circulatory failure, paralysis, and albuminuria.

Ætiology.—Diphtheria is commonest in temperate climes. Human carriers are the cause of its endemic prevalence; local conditions being merely contributory. In its seasonal prevalence diphtheria resembles typhoid and scarlet fever, the maximum incidence falling in the autumn and late winter months. An epidemic tendency is noticeable in years of deficient rainfall. Formerly a disease of rural districts, diphtheria is now endemic in cities and shows a tendency to local epidemic outbursts. Its heaviest incidence is on children between the ages of 2 and 5 years. New-born infants are rarely attacked. Many cases occur in adults, and rather more females than males are affected.

Catarrhal conditions of the throat predispose to the infection; convalescents from measles and scarlet fever, and in less degree those recovering from whooping-cough and influenza, are liable to contract the disease, which in the case of recent measles or scarlet fever may assume a particularly severe form. A progressive increase in infectivity and severity is often noticed during epidemics. The immunity afforded by diphtheria is short-lived; relapses are rare. Second attacks may occur.

The disease is highly contagious, and infection is by direct or indirect contact. It is seldom air-borne even over a short distance. The organisms reside in the secretions from the nose and throat, in detached shreds of false membrane, and at times in discharges from the ears, the vulva, infected wounds or skin lesions.

Direct infection may result from kissing, or the reception of droplets of fluid ejected by speaking, coughing or sneezing. Indirect infection may be caused by eating or drinking utensils, handkerchiefs, towels, throat spatulas, clinical thermometers, toy trumpets, slate pencils and the like. The diphtheria bacillus readily grows in milk and produces no suspicious changes; milk thus may serve as a vehicle for spread of the disease. There is no evidence that it is conveyed by drinking water. The diphtheria of birds, cats and most other animals has not proved communicable to man and is due to a different organism, but virulent diphtheria bacilli have been found in nasal discharges and open sores of horses.

Diphtheria bacilli retain their virulence for long periods if protected from sunlight and from currents of air; hence the possibility of transmission by fomites. Sterilisation by boiling water or in the steam chamber is quite effectual.

Carriers.—Convalescents may harbour virulent bacilli in their throats, as also may others who have been in contact with the infection. Most are free from bacilli 4 or 8 weeks after the commencement of the disease, but in some the carrier state becomes chronic. The dangerous chronic carrier is usually an immune person, as shown by a negative Schick reaction. The presence of bacilli in the throat secretions of carriers is apt to be intermittent. All carriers are not equally effective distributors of the disease; intimate contact and addiction to such habits as kissing, sneezing, spitting and pencil-sucking are important in this respect. The nasal carrier is believed to be an especial source of danger. Among school children 80 per cent. of the carriers are between 5 and 8 years of age, and male carriers are two or three times more common than female. Throat and nose operations on carriers may be followed by clinical diphtheria. In the search for carriers, pallor, unhealthy tonsils, and nasal discharge are important indications, as also a history of recent sore throat. Skin carriers are the subjects of eczematous or impetiginous lesions or whitlows. The discovery of bacilli which morphologically resemble diphtheria bacilli does not necessarily prove they are virulent. Bacilli recovered from the throat are rarely harmless, but those recovered from the anterior nares, from discharging ears and from the skin often prove to be non-virulent when tested on guinea-pigs.

The Klebs-Loeffler bacillus is a non-motile, Gram-positive, non-sporing organism which grows as a diplo-bacillus and shows a great tendency to become segmented or clubbed. The bacilli are slender rods, straight or slightly curved, and of varying length and thickness. In films they often show a characteristic grouping which recalls the letters of the Chinese alphabet. Both long and short forms occur, the length varying from 2 to 6 μ. The segmented appearance of the protoplasm is relied upon for morphological identification. A rapid diagnosis may be made from smears prepared direct from the throat, but it should be confirmed by examination of a film made from a young (6 to 18 hours) culture on blood serum or Loeffler's medium. Diphtheria bacilli ferment glucose with formation of acid, but fail to ferment saccharose. The true bacilli have been divided into *gravis*, *intermediate* and *mitis* varieties, according to their virulence. Differences in growth on a special blood-tellurite medium, coupled with starch-fermenting power in the *gravis* type and a hæmolytic tendency in the *mitis* variety, are the chief distinctive features.

Pseudo-diphtheria bacilli, which, although identical in appearance, with diphtheria bacilli, are non-virulent, are frequently found in the nose and ear, more rarely in the throat. Another non-virulent organism of the same group is Hofmann's. This appears in smears as a diplo-bacillus, the elements of which are short, squat and wedge-shaped with apposed bases. It stains uniformly throughout, and is shorter than even the shortest varieties of the diphtheria bacillus. These distinctions apply only to young cultures. Hofmann's bacillus does not produce acid in glucose, or in saccharose media, and is thus further distinguished. The xerosis bacillus, obtained from the conjunctiva, also resembles the true diphtheria bacillus, but it produces acid both in glucose and in saccharose media.

The crucial test of the identity of the diphtheria organism is the prevention of the local or general action of an injected broth culture by the previous injection of diphtheria antitoxin into the test animal.

In the throat, diphtheria bacilli are often associated with streptococci, staphylococci, or the fusiform bacilli and spirilla described by Vincent. Of these, streptococci are most important, as cases of septicæmia have been found due to them. Diphtheria bacilli themselves rarely become disseminated in the blood stream or internal organs.

Pathology.—The constitutional disturbance caused by diphtheria is toxæmic, toxins but not bacilli being absorbed from the primary lesion, probably by the lymphatics. The extent, thickness, persistence and situation of the membrane determine the degree of toxæmia produced. In the formation of membrane, epithelial necrosis first occurs and is followed by inflammatory effusion from the subjacent tissues. This gives rise to the membrane in which stratified fibrin entangles epithelial cells, blood-cells and leucocytes. Nearly the whole of the process occurs outside the basement membrane. Bacilli are found in the false membrane and necrotic material, but not in the healthy tissues beneath. Recently formed membrane is firm in texture and has a glistening or somewhat gelatinous appearance. The tonsils are the common sites of the first membrane formation, but the faucial pillars, the soft palate, the pharynx, the epiglottis and the larynx may be implicated. Extension from the larynx along the trachea and main bronchi is not uncommon, but coherent membrane is rarely found in the bronchioles. Diphtheritic membrane is much more firmly adherent to the mucous membrane of the fauces than to the epiglottis, the larynx and lower air passages. Its appearance in the cavity of the mouth, on the tongue or lips is rare, and even more rare is its occurrence in the œsophagus, stomach or small intestine. The conjunctiva and occasionally the vulva, or a cutaneous abrasion or a surgical wound may become infected. In this connection it must be remarked that streptococci, pneumococci, and the virus of glandular fever can on occasion produce false membrane.

Apart from the membrane the morbid appearances in diphtheria are not distinctive. The condition, however, of the heart muscle is of peculiar interest. Even in cases in which the myocardium appears healthy to the naked eye, special staining will show extensive infiltration of the muscle fibres with minute granules of mobilised fat. In advanced cases, patches of myocardial degeneration and perivascular aggregations of leucocytes become apparent. The cavities of the heart may be dilated, the muscle flaccid and friable, and intracardiac thrombi, some obviously ante-mortem, may be found in the recesses of the auricles and ventricles, particularly on the right side.

The stomach may be acutely inflamed, with mucosal hæmorrhages and erosions.

The lesion in the kidneys is a degeneration of the epithelium of the tubules, but glomerular involvement may also be present.

Broncho-pneumonia is not uncommon in extensive faucial and in laryngeal infections, it is usually due to secondary invaders. Emphysema or pulmonary collapse may occur where respiratory obstruction is severe, and massive collapse of the lung may result from paralysis of the respiratory muscles.

In the nervous system, the essential lesion is a parenchymatous degeneration of the peripheral nerves which is patchy in its distribution. Chromatolytic changes are found in the vagal nuclei and in the anterior cornual cells of the cord. The cerebro-spinal fluid is normal.

The lymphoid tissues of the body often show a reaction, Peyer's patches being swollen and the spleen slightly enlarged. The liver, too, may be swollen from venous stasis and show slight toxic degeneration of its cells.

Petechial hæmorrhages in the skin, serous membranes, heart wall, and diaphragm are characteristic of hæmorrhagic diphtheria. Extensive effusions of blood sometimes occur.

Symptoms.—The incubation period may not exceed 24 hours, more commonly it is 3 or 4 days, but a carrier may harbour virulent bacilli for a considerable time before showing signs of infection. The fauces are most often the site of the disease, next in frequency come the naso-pharynx, the nasal passages, the larynx and trachea. Infection of the genital mucous membrane and of wounds is exceptional and of the intact skin rare.

Faucial diphtheria may occur in any degree of severity, from a mild catarrhal inflammation, the identity of which is only established by bacteriological examination, to a widespread infection in which membrane invades not only the whole throat but also the naso-pharynx, nose, larynx, and, rarely, the mouth, either simultaneously or in succession.

Invasion may be characterised by malais, headache, anorexia and soreness of the throat. Vomiting occurs occasionally and sometimes shivering; rigor is rare. In children, the onset is particularly insidious, discovery of membrane often being the first intimation of the disease. The exudate in mild cases is often limited to a patch on one or both tonsils, sometimes on the uvula or pillar of the fauces, sometimes on the soft palate. More rarely the posterior pharyngeal wall is first attacked. Special characteristics of the membrane are its elevation above the general surface, its well-defined edge, its glistening or pearl-grey colour, and its tendency to rapid spread. At first it is separable without bleeding, but later free oozing of blood occurs when it is forcibly detached. Multiple patches on the tonsils may, in the early stage, simulate follicular tonsillitis, but the patches tend to spread and fuse; limitation to one tonsil should always arouse suspicion.

Pyrexia is moderate or absent in mild infections, enlargement of the submandibular glands is slight, and early albuminuria so characteristic of grave attacks may be wanting.

When faucial diphtheria is severe it constitutes a very serious form of the disease with a high mortality. The grave form is more common in children than in adults and may develop very rapidly. The membrane is thick, tough, and adherent, sometimes much discoloured. It covers the swollen fauces and may extent widely over both aspects of the soft palate and on the pharyngeal wall. Nasal discharge points to implication of the naso-pharynx and nose. Rarely extension occurs along the hard palate and into the sulci at the sides of the tongue. Secondary invasion of the epiglottis and larynx is not uncommon. The cervical glands become swollen and tender, and periadenitis may extent and involve the neck in a collar of cellulitis (bull neck). The subcutaneous tissues may undergo widespread necrosis and the skin become thinned and much discoloured. A brownish or bloody nasal discharge excoriates the nostrils and the upper lip. Nasal respiration is obstructed and deglutition difficult. The breath has a sickening odour, and the face is puffy or becomes ashen in colour. The skin is dry and the extremities are cold. A slight general cutaneous œdema may make its appearance. The patient is restless and sleepless but apathetic. Bleeding

is easily induced by interference with the edges of the membrane, and epistaxis may occur. Fever is not proportionate to the gravity of the disease; in the worst cases the temperature is subnormal. Albuminuria is usually profuse and the quantity of urine secreted may be very small, but uræmic symptoms are rare. A steady and progressive circulatory failure, characterised by a falling blood pressure and feebleness of the heart's sounds, is an ominous feature. The pulse may become soft, irregular or quite imperceptible. Respiration is rapid and shallow. Vomiting often sets in before the end. Broncho-pneumonia can rarely be recognised by physical signs, but is often present. Death may occur within a week of the onset; sometimes, however, under the influence of antitoxin the membrane clears and the faucial swelling subsides, but acute circulatory failure may still be imminent, death often occurring during the latter half of the second week. In those who escape, widespread paralysis is a common sequel.

Laryngeal diphtheria.—Infection of the larynx may be primary, but is usually a sequel of faucial infection. Essentially occurring in childhood, its frequency increases up to the fourth year of life, after which it progressively declines. The presence of membrane, even in the smallest amount, on the tonsils or fauces will afford a positive indication of the nature of the laryngitis. Failing this a diagnosis is made by swabbing, not the tonsils, but the pharynx or larynx; but treatment must not be delayed pending the result. Hoarseness and croupy cough are early symptoms, soon followed by paroxysms of inspiratory dyspnœa due to laryngeal spasm, with characteristic stridor and recession of the chest wall. During the paroxysms the patient is agitated, sweating and perhaps cyanosed. The cough is loud and croupy. With relaxation of the spasm dyspnœa may cease and the child fall asleep from exhaustion. At first the paroxysms are mainly nocturnal, later they become more frequent and more prolonged, until finally obstruction is continuous and mechanical. Extraordinary recession of the sternum and lower ribs may then accompany the efforts to respire. The body assumes a leaden hue and death occurs from slow asphyxia. In rare instances the paroxysms of dyspnœa and cough culminate in the expulsion of membranous casts of the larynx, trachea or larger bronchi. The absence of toxæmic symptoms when membrane is limited to the larynx and lower air passages is very striking.

Laryngeal diphtheria may run its fatal course in a few days. In infants its duration may be less than 24 hours. In favourable cases the condition subsides under prompt treatment. Should obstruction persist after tracheotomy or intubation, the presence of membrane in the trachea or larger air passages should be suspected; when, however, the bronchioles are blocked, the character of the dyspnœa is quiet rather than violent. Laryngeal diphtheria in a mild chronic form is a rarity.

Nasal diphtheria.—A muco-purulent or blood-stained nasal discharge may be the only evidence of diphtheria in infants and fever convalescents. Infection may be naso-pharyngeal or purely nasal. The former is grave, as toxæmic symptoms may be pronounced, whilst localised nasal infection is more often benign. In such cases a small patch of membrane may, perhaps, be found on the septum. Possible implication of the nasal accessory sinuses should be remembered. As already mentioned, bacilli from the nose may prove to be non-virulent. Foreign bodies in the nose have been found associated with persistent nasal diphtheria.

Conjunctival diphtheria is usually the result of direct inoculation, but may extend from the nose. It may simulate a mild, simple conjunctivitis, or membrane may form on the inner aspect of the lids. There is a grave form with extreme inflammatory infiltration of the conjunctiva which may lead to sloughing of the cornea and destruction of the eye.

Vulval, vaginal and preputial diphtheria.—Vulval infection may be secondary to diphtheria of the fauces, infection being conveyed by the fingers, or it may be primary. Sometimes it is seen in puerperal women. It is of insidious onset, and the membrane looks like a slough on the inner surface of one or both labia. The inguinal glands are enlarged, and confusion with erysipelas, chancre or gonorrhœa is possible. Severe toxæmia may ensue. The vagina may be infected with the vulva. Preputial diphtheria may follow ritual circumcision. Infection of the puerperal uterus and of the male urethra is rare. Infection of the umbilicus may occur in the new-born.

Diphtheritic infection of wounds is not common, and membrane formation is not invariable. The wound may merely be dry and grey and the adjacent glands swollen. Bacteriological confirmation is necessary. Paralysis may be local in distribution.

Cutaneous diphtheria.—Slight infection of the macerated skin at the margins of the nostrils and mouth is frequent and diphtheritic whitlow is not rare, the finger possibly being infected by sucking. Sometimes the raw surfaces left by eczema, herpes, or impetigo, become secondarily infected, and membrane may form, but skin diphtheria may occur without this distinctive sign. Gangrenous varicella and extensive gangrene allied to noma has also been attributed to the action of the diphtheria bacillus. Before skin cases are accepted as genuine, rigorous bacteriological proof is essential.

Septic diphtheria.—The ordinary grave case of diphtheria may be looked upon as toxæmic or malignant. The septic type of case is characterised by pulpy discoloured membrane and great inflammatory œdema at the site of infection, accompanied, it may be, by ulceration, cellulitis, or even gangrene. The adjacent lymph glands are much swollen, periadenitis is marked and suppuration may ensue. Erythematous or measly rashes may appear on the extremities. Constitutional symptoms are severe and the prognosis grave, chiefly, it is alleged, because diphtheria antitoxin has no influence on the septic element, which may be a hæmolytic streptococcus.

Hæmorrhagic diphtheria.—Hæmorrhagic symptoms supervening during the acute stage indicate an infection of a severe type. Blood may ooze from the edges of the membrane, and epistaxis occur. This in itself is not necessarily serious, but the tendency to bleed may be more widespread, bruises appearing on the body and bleeding occurring around and along the track of the antitoxin needle. The conjunctivæ may become suffused with blood, and hæmorrhage may occur from the stomach or bowel. Hæmaturia is rare. Small cutaneous petechiæ are by themselves of most sinister omen. They are insignificant in appearance and easily escape detection on account of their smallness and tendency to occur on the neck and trunk where clothing conceals them.

Blood changes.—A polynuclear leucocytosis is common and reaches its acme at the height of the disease. Sometimes the red cells are in excess of normal and the specific gravity of the blood increased, indicating an oligæmia. Leucocytosis may be absent in very mild and also in very grave infections.

The presence of myelocytes is also characteristic, and their appearance in large numbers indicates a severe toxæmia and a bad prognosis.

Complications.—The chief are circulatory failure, paralysis, albuminuria and pulmonary inflammations. Relapse sometimes occurs.

Acute circulatory failure is a justly dreaded occurrence. Apart from asphyxia and from respiratory paralysis it is responsible for all the deaths. In diphtheria, excluding the mildest cases and those in which respiratory obstruction exerts its modifying influence, there is from the first a progressive fall of blood pressure, the systolic readings being affected earlier than the diastolic. Recovery is very rare when the systolic reading falls below 65 mm. The fall in pressure is said to be accompanied by a fall in volume and increased concentration of the blood. Vascular relaxation is believed to account for the early fall in pressure, the effect of myocardial weakness appearing later. The condition culminates in attacks of acute circulatory failure. Where systematic pressure readings have not been taken, minor irregularities and intermissions of the heart's action often afford the first warning. True respiratory or sinus arrhythmia, which is so common in childhood and often is exaggerated in diphtheria, should not be confounded with the condition now under consideration. Tachycardia and bradycardia are both disquieting signs. The heart sounds become modified, the first becoming short and soft and the second somewhat accentuated. Reduplication and gallop-rhythm may occur. Vomiting without obvious cause is always a danger signal. The characteristics of the acute attack are great irregularity and feebleness of the pulse, præcordial or epigastric pain, restlessness, rapid shallow respiration, slight cyanosis and a sub-normal temperature. The mind remains clear. Dilatation of the heart and increase in the size of the liver may be evident. Actual dropsy is rare, but sometimes slight œdema of the face, chest and feet appears. Albuminuria may supervene or, if already present, be much increased; partial suppression of urine occurs. Death often results with great suddenness, and should the first attack be survived, which is unlikely, a second or even a third may prove fatal. Rarely recovery ensues.

Death from circulatory failure is an early sequel of severe faucial infections, occurring at the end of the first or in the course of the second week. Cardiac failure occurring at a later stage of the disease is often associated with severe paralytic phenomena, and in some cases, at all events, is believed to be of nervous rather than myogenic origin. Extra systoles, heart-block and auricular fibrillation have at times been demonstrated. The absence of residual valvular or myocardial lesions after diphtheria is remarkable.

Diphtheritic paralysis occurs in from 15 to 20 per cent. of cases. It is more often localised than general, and rarely complete in degree. Children suffer more frequently and more severely than adults. As a general rule the extent and severity of the palsy are proportional to the amount of membrane which was present. Exceptionally, paralysis of diphtheritic type occurs in the absence of recognised infection. The usual time of onset is the end of the third or beginning of the fourth week of the disease, but in grave infections it may even set in before the fauces are clear of membrane. Widespread paralysis rarely declares itself before the end of the fourth week, and paralysis of the ataxic type, which is rare, often does not appear until the second or even third month. For a detailed description see pages 1781–1783.

The limited form of diphtheritic paralysis is transitory, its duration being measured by days or weeks, but the more widespread paralysis may last for months or the best part of a year before recovery is complete.

Hemiplegia sometimes occurs in diphtheria and is due to occlusion of the middle cerebral artery, usually by an embolus. In most cases this paralysis is more or less permanent. Much more rarely an embolus from the heart lodges in a main artery of a limb, producing gangrene.

Albuminuria is of common occurrence, but in mild or doubtful cases its absence is not sufficient to negative the diagnosis. It is most likely to be found about the tenth day, but appears earlier and in greater quantity in grave cases. In those who recover, its presence is transitory and no grave damage to the kidneys results. At times casts and a little blood may be found in the urine, particularly in toxic or asphyxial cases. Acute circulatory failure greatly increases the albuminuria and may lead to actual suppression of urine. Acetone often appears in the urine during severe attacks.

Pulmonary Complications.—Bronchitis and broncho-pneumonia may accompany severe faucial diphtheria, but are more common when the larynx is implicated. The cause is more often a secondary infection than the diphtheria bacillus. Febrile disturbance, great dyspnœa, cough, and lividity are the signs which should suggest implication of the lung. Auscultatory signs are often equivocal, owing to laryngeal obstruction or the presence of a tracheotomy tube. Massive collapse of the lungs may occur in paralytic patients and is often mistaken for acute circulatory failure, pneumonic consolidation or pleural effusion. Some degree of acute emphysema is usually present when the larynx is obstructed, and surgical emphysema of the mediastinal and subcutaneous tissues may follow a difficult tracheotomy. As sequels of diphtheria, lobar pneumonia, pleural effusion and empyema are rare.

Otitis media is exceptional and seldom serious. In this respect it stands in sharp contrast to the otitis of scarlet fever. Diphtheria bacilli recovered from the discharge are often non-virulent (perhaps in 50 per cent. of the cases). Diphtheritic membrane is sometimes formed in the auditory meatus.

Relapse of diphtheria is rare. It occurs in little over 1 per cent. of the cases and usually is mild, the membrane being limited to the tonsils and rarely spreading to other parts.

Diagnosis.—Every inflamed throat, or nasal discharge, particularly in a child, should be regarded with suspicion, and clinical diagnosis supplemented by bacteriological examination before antiseptics are applied. Definite membrane on one or both tonsils or adjacent parts of the throat is characteristic of diphtheria. Tonsillar inflammation, if accompanied by hoarseness or rhinorrhœa or albuminuria, is highly suggestive. Some diphtheritic throats are very œdematous and painful, but as a rule pallor of the mucous membrane and absence of pronounced fever and pain are striking features of the disease.

The differential diagnosis between scarlet fever and diphtheria is discussed on p. 73. Simple tonsillitis is usually bilateral, and the exudate, which is soft and crumbling rather than membranous, is follicular and limited to the surface of the tonsils. Pyrexia and constitutional disturbance are more pronounced than in diphtheria, and the tongue is heavily coated.

Peritonsillar abscess is more characteristic of simple tonsillitis and the secondary tonsillitis of scarlet fever. It seldom occurs in diphtheria.

Vincent's angina may produce a greyish film of exudate on one or both tonsils, and even invade the adjacent parts of the faucial pillars and the soft palate, but the process is rather a shallow necrosis than a true membrane formation. Ulceration may be evident at the centre of the deposit; sometimes it is widespread and destructive. The mucous membrane of the gums and cheeks may also be attacked. The breath has a peculiar and offensive odour, but diagnosis should never be based on this alone. The large fusiform bacilli and spirilla described by Vincent can be demonstrated.

Double infections with diphtheria and Vincent's organisms are not at all rare. Thrush, which produces an exudate like milk curd, is recognised by detection of the characteristic mycelium. It is a disease of infants and greatly enfeebled adults.

Membranous angina may occur in glandular fever, leukæmia, or agranulocytosis. For the differentiation of these, blood-counts as well as throat swabbings are necessary.

Syphilis.—Both in adults with the acquired and children with the inherited disease the inflamed throat of secondary syphilis is a cause of confusion. The throat is painful and full of mucous secretion. Filmy patches appear on the tonsils and pillars of the fauces. The tonsillar glands are swollen and there is little or no fever. The rapidity with which ulceration and perforation of the palate occur in some cases is striking. The diagnosis is made from the history, the presence of other signs of syphilis, failure to find diphtheria bacilli, a positive Wassermann reaction and prompt response to vigorous anti-syphilitic treatment.

Other conditions which simulate faucial diphtheria are erysipelatous inflammation, herpes of the soft palate and lesions due to steam, boiling fluids, caustics or tonsillectomy.

Laryngeal diphtheria.—Croupy cough, hoarseness, and stridor in a child will always suggest diphtheritic infection. Examination may show membrane on the fauces. By forcible depression of the base of the tongue with a spatula, the epiglottis may often be seen and membrane possibly recognised on its edge or surface. Rarely fragments of membrane are ejected on coughing, or there may be a history of contact with the disease. All doubtful cases should be treated freely with antitoxin, pending confirmation by examination of a swab taken from the pharynx as near the glottic aperture as possible.

Other forms of laryngitis have to be differentiated. They are (1) the laryngitis of early measles, distinguished by history, catarrhal symptoms, and Koplik's spots. (2) Simple catarrhal laryngitis; in this bacteriological examination is most essential. The voice may be hoarse, and the cough croupy; nocturnal spasms of dyspnœa may occur. Enlarged tonsils and adenoids are often present, and sometimes the history of previous attacks is obtained. (3) The glottic spasm of laryngismus stridulus is also definitely paroxysmal, but although the child crows the voice is not hoarse nor is the stridor persistent. Rickets, tetany and convulsions are the accompaniments in many cases.

Retro-pharyngeal abscess, when low down, produces considerable laryngeal obstruction. Digital examination of the back of the pharynx reveals its presence; sometimes the bulging may be seen on inspecting the fauces.

Rare causes of laryngeal obstruction are congenital laryngeal stridor, congenital syphilis, œdema of the glottis in renal disease, or resulting from inhalation of steam or other irritants, foreign bodies in the larynx, and papillomatous growths. These forms of obstruction are differentiated from diphtheria by the history, by careful inspection of the fauces, followed by digital examination, by general examination of the patient and by the negative results of bacteriological examination. In adults the laryngoscope will give useful information. Direct laryngoscopy is of great value.

Prognosis.—The important indications yielded by determination of the extent and position of the membrane have already been mentioned: the more extensive and more persistent this is, the greater is the risk of severe toxæmia. Cases where the membrane is limited to one, or to parts of both tonsils are likely to be mild; when both tonsils are completely covered the attack is more grave, but recovery is still probable; when the fauces and naso-pharynx are extensively involved, the outlook is very serious. The great mortality of laryngeal diphtheria is due to asphyxia and broncho-pneumonia, absorption of toxin from this region being small. Diphtheria limited to the nose and not involving the naso-pharynx has a low mortality.

Enlargement of the cervical glands is more or less proportional to the extent of the lesion in the fauces and naso-pharynx, and has the same prognostic importance. The efficiency of antitoxin treatment and the day of its first administration have a most important influence. The mortality is almost negligible when antitoxin is administered on the first day of the disease, but it increases progressively to 18 or 20 per cent. if administration is delayed to the fifth or subsequent days.

Age also has a great effect, the disease being very fatal to children in the first year of life, and much more serious in children under 5 than in those over that age. Septic attacks with much pallor, copious nasal discharge, considerable glandular enlargement and profuse albuminuria have a very bad prognosis.

Hæmorrhagic symptoms, other than slight bleeding from the edge of the membrane and possibly epistaxis, are grave; particularly so, minute cutaneous petechiæ. Cases such as these hardly ever survive. Repeated vomiting after the initial stage, and signs of acute circulatory failure are most ominous. The chief danger of paralysis, when this ensues early, is its association with acute circulatory failure, but paralysis of the bulbar type is in itself very fatal. Failure of the muscles of respiration and liability to broncho-pneumonia and pulmonary collapse constitute the chief dangers of generalised paralysis. If the patient survives, paralysis terminates in complete recovery, but hemiplegia, which is of vascular origin, may be permanent.

Treatment.—PROPHYLACTIC.—Convalescents should be isolated for not less than 4 weeks from the commencement of the disease, or until three negative bacteriological examinations at intervals of a week have been obtained. The presence of inflammatory conditions or discharges from the throat, nose, eyes or ears is an indication for further detention. Skin eruptions and whitlows should be carefully treated.

The period of quarantine advised is 12 days. This may be supplemented by bacteriological examinations. Children from an infected house should not be allowed to attend school. Contacts in the home or school often become carriers, and should be bacteriologically examined. Clothing and

utensils which have been in contact with the sick should, of course, be disinfected.

When diphtheria breaks out, contacts should be examined for unhealthy conditions of throat, nose, ears or skin, and bacteriological examination made in all instances, if possible. Opinion with regard to the desirability of prophylactic injections of antitoxin is not unanimous. The *symptoms* of diphtheria may be prevented in contacts by the injection of 500 units of antitoxin, but this method fails if the subject is already incubating the disease, and only affords protection to others for some 3 or 4 weeks. It should be realised that antitoxin does not prevent *infection*, but only the toxic results of infection. It militates against active immunisation, and may produce a condition of hypersensitiveness to serum, which may have to be used subsequently.

For these reasons, the best authorities are against prophylactic injections of antitoxin in contacts and in favour of repeated examinations for signs of development of the disease, when antitoxin can be administered at once. Meantime, immunisation of susceptible contacts (*vide infra*) can be initiated, since there appears to be no negative phase induced.

In the Schick test we have a means of determining whether an individual is susceptible to diphtheria. If a local inflammatory induration from 1 to 2 cm. in diameter follows the injection of a minute quantity of diphtheria toxin *into* the skin, susceptibility to the infection is indicated. One-fiftieth of the minimum lethal dose (M.L.D.) of toxin for a guinea-pig of 250 grammes weight, in 0·2 c.c. of normal saline is the standard dose. At the same time, but at another spot, an intradermic injection of heated, and therefore inactive, toxin is made, to discount a " pseudo " reaction due to the foreign protein in the solution of toxin. The absence of a reaction to the active toxin indicates the presence of more than one-thirtieth of a unit of antitoxin per c.c. in the blood, and is a sign of immunity. The injections are usually made into the skin of the forearms. The reaction takes 24 to 36 hours to develop, and another week to subside. Four types of reaction are possible : (1) Negative, (2) Positive, (3) Negative and Pseudo, and (4) Combined Positive and Pseudo. These must be discriminated with care. The best time for reading the test is 36 hours after injection, and again at the end of a week when false reactions will have faded and late positive reactions will be detected.

For immunisation, diphtheria toxin, guarded by antitoxin, was originally used. Later, toxin, converted to toxoid by incubation with formalin (*anatoxine*), replaced this. Toxoid-antitoxin floccules, precipitated by interaction of toxoid and antitoxin produce little or no reaction and are effective. For the immunisation of children, alum-precipitated toxoid (A.P.T.) is now recommended. Two doses (of 0·5 c.c.) are given intramuscularly, with an interval of 4 weeks between, the first dose acting both as an antigen and as a detector of sensitive individuals. For adults, who are more liable than children to reactions, toxoid-antitoxin floccules (T.A.F.) are preferable, three injections (1 c.c., 1 c.c. and 1·5 c.c.) being administered, with intervals between them of 3 or 4 weeks. Susceptibility to reaction may be detected by intradermal injection of 0·2 c.c. of diluted toxoid (Moloney test). The development of active immunity takes about 6 weeks. This immunity is protracted, but its exact duration cannot yet be specified. Most children under 6 years are susceptible and the ideal time for immunisation is in the

pre-school period, after the first year of life. When the proportion of vaccinated children in a community reaches 70 to 80 per cent. a great reduction of incidence of diphtheria, perhaps to zero, may be expected.

When dealing with outbreaks of diphtheria in wards or institutions, swabs should be taken from the throats and noses of the inmates, and Schick tests performed. The negative reactors are then isolated. They will probably include a dangerous chronic carrier as proved by the virulence test. The positive reactors may be immunised with A.P.T. Virulent bacilli in the Schick positive group indicate precocious carriers or who will soon sicken with the disease.

Chronic carriers are a great source of difficulty. The bacilli cannot be eradicated by local application to the throat or by the administration of antitoxin or vaccines. If the tonsils are unhealthy, they should be enucleated and adenoids removed; this is often successful. Carriers should spend as much time in the fresh air and sunlight as possible. Before condemning a carrier to isolation, the virulence of the organisms should be tested.

CURATIVE.—The patient should be isolated and strict recumbency enjoined. Diphtheria antitoxin must be injected without delay, the result of bacteriological examination not being awaited in any case in which the diagnosis is reasonably certain. It is very important the patient should receive the first dose of serum not later than the third day of the disease; the earlier it is given the better the result, but at whatever stage the presence of membrane indicates prompt dosage. The amount required depends, not on the age, but on the duration of the disease, the extent of the membrane and the degree of toxæmia. For mild cases on the first or second day 8000 units are sufficient; in more severe cases the dose should be 20,000 units. In severe faucial and naso-pharyngeal diphtheria and in infections of the larynx, 20,000 units should be the initial dose, repeated in 12 hours if the membrane still shows a disposition to extend, or the laryngeal symptoms are not relieved. Cases coming under observation after the third day of illness require larger doses than those seen earlier. In very severe infections and those complicated by pulmonary lesions, enormous doses have been recommended; The advocates of these larger doses claim a diminished mortality, a reduction of paralytic complications and a speedier convalescence.

Antitoxin should never be given by mouth or rectum. Intramuscular injection is more effectual than subcutaneous, and should replace it. In severe, advanced, and hæmorrhagic infections, the antitoxin should be given intravenously, undiluted and at blood heat. Injection should be very slow, through a fine needle. The patient is then wrapped in warm blankets, hot water bottles applied, and the foot of the bed raised, since rigor and collapse may follow. Fifty thousand or more units may be given in this way, followed by intravenous injection of 20 grammes of anhydrous dextrose in the form of a 50 per cent. solution in normal saline, supplemented by 20,000 units of antitoxin intramuscularly into the buttock or outer side of the thigh. In cases which do not respond the injection is repeated after 12 hours. Strict aseptic precautions should always be observed.

Antitoxin treatment may be followed by certain sequels due to horse serum. These are less frequent when concentrated antitoxin is used. They usually occur a week or more after injection and take the form of erythematous, morbilliform, or urticarial eruptions, appearing first in the vicinity of the

puncture. Fever, vomiting, arthritic pains or slight joint effusions may accompany the rash. The tonsils may again become inflamed (*angina redux*) and albuminuria may occur. The rashes and other symptoms are transient but may recur. Aspirin often affords much relief, and the cutaneous irritation may be allayed by weak carbolic lotions. On rare occasions rigor, dyspnœa and collapse follow the injection immediately, and death has been known to occur. These symptoms are anaphylactic in nature and may occur if the patient has been sensitised by injection of serum a few weeks previously, or quite apart from this. Asthmatics are said to be particularly liable to them. When it is necessary to administer antitoxin in such circumstances, a preliminary injection of 5 minims should be given and the effect watched. If no symptoms occur within an hour the full injection may be employed, otherwise desensitisation is necessary.

Absolute recumbency is essential in the treatment of diphtheria. For the mildest case a fortnight is not too long, in the average case at least a month, and for severe infections longer. When the patient is first allowed to sit up in bed the effect on the pulse should be carefully noted. No patient should be allowed to sit up whose pulse is irregular or who has recently vomited. The detection of paralytic symptoms is also an indication for rest.

Local applications to the fauces and nose are of minor importance. In cases characterised by fetor the free chlorine lotion is of use. When douching is resisted it is better to omit it altogether.

In laryngeal diphtheria prompt administration of antitoxin and the use of a steam tent will generally obviate the necessity of operative interference; but tracheotomy, intubation or laryngeal aspiration should not be postponed, if restlessness, dyspnœa and recession of the chest wall are present, or paroxysmal dyspnœa has supervened.

Intubation is suitable for the milder type of case, but constant skilled supervision is necessary, as the tube may be ejected. As a rule, tracheotomy is preferable, especially if the fauces and naso-pharynx are much involved. Tracheotomy as a sequel to intubation has a very high mortality on account of the class of case in which it becomes necessary. After tracheotomy or intubation the patient is usually placed in a steam tent and the arms secured by light splints or other means. Cough on swallowing is obviated by using thickened foods or by nasal feeding. A method of feeding with the head lying lower than the body is often successful in intubated patients. If all goes well an attempt should be made to dispense with the tracheotomy or intubation tube on the third day, sometimes even sooner. Patients must be watched constantly when the tube is first removed. In cases where the tracheotomy is dry and no secretion occurs, an alkaline spray is useful.

Circulatory failure is treated by removing all pillows, raising the foot of the bed on blocks and applying a binder to the abdomen. The most absolute rest and perfect quietude are essential. A combination of atropine, strychnine and adrenaline has the best reputation as a circulatory stimulant in these cases (atropine sulphate, gr. $\frac{1}{200}$; strychnine sulphate, gr. $\frac{1}{100}$; adrenaline solution, 1 in 1000, min. 5). The solution is made up to 10 minims with sterile water and injected every 4 hours or more often if necessary. At the same time, as vomiting often precludes feeding by the mouth, a 5 per cent.

solution of glucose in hot normal saline should be given by the bowel. Other circulatory stimulants and brandy are also advocated. When marked acetonæmia is present, 10 grains of sodium bicarbonate dissolved in 1 ounce of water should be given by mouth or rectum every 4 hours.

Paralysis calls for careful nursing and feeding, with avoidance of muscular exertion, but patients with palatine paralysis only may be allowed up after 10 days if the condition is stationary. Massage and electricity may be useful during convalescence, but should be avoided in the early stages. Hypodermic injection of strychnine is possibly of some use. The administration of vitamin B_1 (aneurine hydrochloride; thiamine hydrochloride, U.S.P.) is said to expedite recovery. The daily administration of antitoxin in doses of 1000 to 2000 units is advocated, but is of very doubtful utility. Extensive respiratory paralysis necessitates artificial respiration with a Drinker or Bragg-Paul apparatus. Active collapse of the lung in diphtheria may be mistaken for acute circulatory failure if its special diagnostic signs are not borne in mind.

During the acute stage of diphtheria and also when albuminuria is present, milk is the best food. Solids may be allowed quite early in convalescence. When swallowing provokes coughing, the milk should be thickened with isinglass or cornflour. When pharyngeal paralysis is present, the patient should be fed by rectum, or better, through a large soft œsophageal tube or by nasal catheter.

The occurrence of anaphylaxis after injection of antitoxin is treated by injection of adrenaline, and by artificial respiration; by some adrenaline is given before injection of serum, as a prophylactic.

WHOOPING-COUGH

Synonym.—Pertussis.

Definition.—An acute specific disease of high infectivity, characterised by catarrh of the respiratory tract, combined with periodically recurring laryngeal spasms of distinctive type and other signs of nervous excitability.

Ætiology.—Whooping-cough is mainly a disease of temperate climates, being rarer and less severe in hot countries. Spring and autumn are the seasons of its maximum prevalence, and also of its greatest mortality, chiefly owing to respiratory complications; but the disease may also occur in the warmer months, even in epidemic form. It is more prevalent in cities and industrial centres than in the population of rural districts. Persons of all ages, if unprotected by a previous attack, are susceptible to the infection; a number of cases have been recorded in patients over 60 and a few in patients over 80 years of age, but whooping-cough is essentially a disease of childhood. Moreover, it shows a stronger tendency to attack children under 2 years than does any other specific disease, and the death-rate is highest for this group, especially in infants of the first year. Most attacks occur before the age of 10 years. The fœtus *in utero* has been known to contract the infection from its mother, and to show the characteristic symptoms soon after birth. More females than males are attacked. The frequency with which whooping-cough follows an attack of measles is noteworthy.

Infectivity is greatest during the catarrhal and early paroxysmal stages;

but its exact duration is a matter of dispute. On rare occasions convalescents are said to have acted as carriers of the disease.

The infection is usually direct, being conveyed by the mucous droplets expelled by the cough. Since the bacillus can resist drying for several weeks the disease may also be conveyed by fomites, but this is uncommon. One attack almost invariably confers lifelong immunity.

Bacteriology.—Of the various organisms which have been alleged to be the causal agents, the bacillus of Bordet and Gengou (*Hæmophilus pertussis*) has the strongest claims to acceptance. This is a minute, slender rod closely allied to the bacilli of the influenza group. It is Gram-negative, and only flourishes on artificial media which contain blood or serum. It grows best at blood heat. Cultures are most easily obtained from the small pellets of viscid mucus which are expectorated at the end of a paroxysm of coughing. The blood of convalescents agglutinates the bacilli.

There are no post-mortem appearances which are distinctive, the changes found after death being due to complications. Of these, congestion of the air-passages and broncho-pneumonia are the most common, and are accompanied by general acute vesicular emphysema. The tracheo-bronchial lymph glands are usually soft and swollen.

The paroxysmal cough is attributed to hyperæsthesia of the respiratory mucous membrane and to heightened excitability of the vagus nerve.

Symptoms.—The incubation period is difficult to fix with accuracy, owing to the insidious nature of the onset and the delayed appearance of the characteristic whoop, but it is most probably 13 to 15 days. Extremes of 3 days and over 3 weeks have been claimed. During a typical attack three stages may be recognised—the catarrhal, the paroxysmal, and the convalescent.

The catarrhal stage lasts from seven days to a fortnight—it is febrile, and in many ways resembles a somewhat severe respiratory catarrh; but the cough is more troublesome and generally accompanied by some sonorous and sibilant rhonchi. Recognition of the disease at this stage is difficult unless the patient is known to have been exposed to the infection. Suggestive signs towards the end of the period are a tendency of the cough to assume a paroxysmal character, with greater severity at night, giving rise to suffusion of the face and occasionally culminating in vomiting. Bacteriological investigation by cough plate and the detection of lymphocytosis will assist early diagnosis.

When the paroxysmal stage is reached the disease is unmistakable. Fever will usually have subsided; but the cough occurs in paroxysmal bouts, often spontaneous, but frequently the result of external stimuli, such as excitement, draughts, the ingestion of food or examination of the throat. Several paroxysms may occur in quick succession with longer or shorter intervening periods of freedom. The victim knows when the cough is impending, and may attempt to suppress it. If lying in bed a child will sit up, if about he may run to his mother or nurse. A brief, deep inspiration is followed by a rapid succession of short coughs, with open mouth and protruded tongue, which are continued until the chest is almost emptied of air. The face becomes congested or livid, the superficial veins are engorged, and the eyes fill with tears. The eyeballs protrude, the skin is bathed in sweat, and suffocation appears imminent; but relief is suddenly afforded by relaxation of the laryngeal.

spasm and the occurrence of the whoop, a long-drawn crowing inspiration, which refills the lungs with air. The paroxysm then recurs, and may be repeated several times, leaving the child perspiring and exhausted. The bout often terminates with the discharge from the air-passages of a pellet of viscid, transparent mucus. A quantity of thin sticky secretion, which is sometimes blood-stained, may also flow from the mouth and nose. During the fits of coughing, which often last for 2 or 3 minutes, the child may faint or become convulsed and insensible. The contents of the stomach are often ejected, and the urine may be voided; in some instances incontinence of fæces occurs. Epistaxis is not uncommon in the more severe attacks. Subconjunctival hæmorrhage may occur, and petechiæ appear in the skin of the eyelids and other parts. Rarely the membrana tympani is ruptured, and blood escapes from the ear In infants asphyxia may occur and call for artificial respiration.

In the early paroxysmal stage the cough is only occasional, but its frequency soon increases, and in a case of moderate severity from 15 to 20 paroxysms occur in the 24 hours; in some attacks, however, they are much more numerous. They are characteristically most frequent and most severe at night.

Physical examination of the chest at this stage will still reveal signs of diffuse bronchitis; but this is now accompanied by a greater or less degree of acute emphysema and a moderate degree of abdominal distension is not uncommon. The forcible protrusion of the tongue over the lower incisor teeth often produces a shallow ulcer on the frænum linguæ.

The duration of the paroxysmal stage is from 3 to 10 weeks, and after this convalescence begins. Whooping-cough is more prolonged in winter than in summer, and its duration is increased if complications ensue. After the whoop has ceased a fresh attack of respiratory catarrh may cause it to reappear; but this should not properly be regarded as a relapse, and does not render the patient again infectious.

The blood shows a leucocytosis even in the early catarrhal stage. Both polymorphonuclear cells and lymphocytes share in the increase; but the lymphocytes are increased out of proportion to the other cells; a typical count would be 15,000 to 25,000 white cells per c.c. with from 50 to 70 per cent. lymphocytes. Myelocytes may also make their appearance. The leucocytosis is said to be increased after each paroxysm of coughing, and the highest counts to be found during convulsions. The supervention of pneumonia increases the polymorphonuclear cells.

Course.—Attacks vary in their severity and duration. Mild infections may run their whole course in a week or two, whilst severe ones may last several months. As mentioned above, the number of paroxysms in 24 hours is some measure of the severity. The danger of supervention of complications is broadly proportional to the severity of the attack. When whooping-cough occurs in the adult the whoop is much less conspicuous, and may be entirely absent, the disease being characterised by violent fits of coughing with a sense of impending suffocation. Cyanosis, vomiting, and even temporary attacks of unconsciousness may occur and subcutaneous ecchymoses appear. The legs may become œdematous and muscle rupture may ensue from the violence of the cough, which retains its paroxysmal character and nocturnal severity. In infants, too, the whoop may be very imperfectly developed.

Complications.—These belong mainly to the paroxysmal stage of the disease—they are partly mechanical and partly inflammatory in nature. The most serious are excessive vomiting, broncho-pneumonia and convulsions.

When the paroxysms of coughing are frequent and severe, excessive vomiting may lead to great emaciation and exhaustion. Diarrhœa and ileo-colitis may also occur, mainly in younger children, and during the summer months.

Pulmonary complications are frequent, and are more common during the winter. A mild general bronchitis with general, but temporary, acute emphysema is the rule, and is of but little moment. Capillary bronchitis or broncho-pneumonia, with pulmonary collapse, is much more serious. It usually occurs at the height of the paroxysmal stage, and is responsible for two-thirds of the deaths. Interstitial emphysema of the lung may result from rupture of an air cell during coughing, but is only likely to be recognised when it overflows into the root of the neck and the connective tissue of the chest wall. Bronchiolectasis is an occasional sequel of the disease.

A single convulsion may prove of little importance, but convulsive states in the form of *whooping-cough eclampsia* constitute a deadly complication, which is seen chiefly in infants and young children. The convulsions occur after prolonged paroxysms of coughing or as a terminal event, but on occasions they may precede a paroxysm or occur in the intervals. Their cause is much disputed. It is tempting to associate them with the encephalitis of measles, mumps, small-pox, and other infectious diseases. Degenerative changes have been found in the nerve cells of the cornu ammonis and basal ganglia, and also in the Purkinje cells of the cerebellum.

Coma or paralysis of varying duration and extent may follow convulsions. Hemiplegia, aphasia, paralysis of ocular nerves, or defects of sight, hearing and intelligence sometimes supervene, and bulbar paralysis and polyneuritis have been recorded. Defect in vision is sometimes due to retinal hæmorrhage or detachment.

The strain of the recurrent paroxysms of coughing may induce dilatation of the right ventricle of the heart, subconjunctival hæmorrhages, cutaneous petechiæ, epistaxis, bleeding from the mouth or ears, hæmoptysis, and hæmorrhage on the surface or less commonly in the substance of the brain. Other results are the appearances of herniæ and prolapse of the rectum.

True nephritis is rare, but albuminuria may appear. Glycosuria is occasionally seen.

An unhealthy condition of the naso-pharynx may persist after the cough has subsided, and no other disease except measles has such a bad reputation as whooping-cough as a forerunner of tuberculous manifestations.

Diagnosis.—In the absence of known exposure to infection, diagnosis may be impossible until the whoop is heard; but the significance of a paroxysmal cough, worse at night and terminating in vomiting, should not be overlooked. The disproportion between the violence of the cough and the accompanying physical signs in the chest is also noteworthy. When broncho-pneumonia does supervene the whoop may cease. In infants the

cough may be paroxysmal and asphyxiating, but the whoop not developed; in such cases, as also in adults when the whoop is absent, the diagnosis may be cleared up by the occurrence of infection in contacts.

Bacteriological diagnosis may be effected by receiving the invisible droplets ejected during a natural paroxysm of coughing on a modified Bordet-Gengou culture medium in a Petri dish, held 6 inches in front of the mouth. The medium consists of defibrinated blood-agar, human blood being used by preference. The growth should be recognisable in 48 to 72 hours as small glistening colonies of minute ovoid, Gram-negative rods or cocco-bacilli, frequently paired. More than one exposure may be necessary. A negative result does not necessarily exclude whooping-cough. The bacteriological method may also be applied to determine the cessation of infectivity, three negative results on successive days being accepted as satisfactory.

The spasmodic cough of bronchial gland irritation and of adenoids is apt to be paroxysmal, but the whoop is wanting. The same observation applies to the obstinately recurrent coughs of influenza and bronchiolectasis. In children, laryngeal inflammation of catarrhal or of syphilitic origin may induce paroxysms of cough and laryngeal spasms, but the tone of the cough at once indicates its laryngeal origin. Conversely, whooping-cough in its early stages, if accompanied by an unusual amount of laryngeal catarrh, may be confused with the laryngitis of measles or of diphtheria.

In the catarrhal stage the malaise, cough, pyrexia and slight fullness of the abdomen with perhaps some irregularity of the bowels, may arouse unfounded suspicions of early general tuberculosis.

The leucocytosis of whooping-cough, which is considerable in the early stages, may prove of assistance in the early diagnosis of the disease, especially if combined with sputa teeming with slender Gram-negative organisms like influenza bacilli. The count should, of course, be compared with that normal for the child's age. An authentic history of a previous attack puts whooping-cough for all practical purposes out of court, second attacks being excessively rare.

The presence of the sublingual ulcer is only to be expected after the incisors have appeared. Occasionally it is seen in other conditions of persistent cough.

Prognosis.—Whooping-cough is a much more serious malady among the children of the poor, and in those suffering from malnutrition, rickets, tuberculosis, or a predisposition to chest troubles, than it is to healthy children in comfortable circumstances. Apart from this, age constitutes the most important prognostic factor. Infants and children under 3 years of age suffer a considerable mortality, which for the first 12 months of life is estimated at 25 per cent. The mortality decreases rapidly after the third year, and after 10 years of age is insignificant. Hence it is found that more than two-thirds of the deaths from whooping-cough occur during the first year of life, the younger the infant the worse being the outlook. Of complications, broncho-pneumonia causes most of the deaths, occurring chiefly in the winter months. In the summer, ileo-colitis comes into prominence.

Convulsions, especially if repeated, are of grave omen. Death at times occurs suddenly from asphyxia due to sustained laryngeal spasm, or from heart failure or intracranial hæmorrhage. When tuberculous lesions are

present these may be stirred into activity by the infection, and especial care is necessary.

A cautious prognosis should be given with regard to paralytic sequels, since in a number of cases these prove permanent.

Treatment.—Isolation should be enforced. Free ventilation with abundance of fresh air is desirable, and gives better results than confinement in a close room and the inhalation of medicated vapours. In the absence of fever, older patients may be allowed up and out as much as possible, provided isolation can be maintained. In suitable weather continuous open-air treatment may be adopted even for those patients who are confined to their beds. It is especially valuable in broncho-pneumonia. A light binder should support the abdomen, and the clothing be loose and not too heavy. When lung complications are present a jacket of gauze tissue should be worn. The diet should be light and digestible, excess of starchy and saccharine food being avoided. When vomiting is persistent it is a good rule to administer food in small quantities shortly after the paroxysms of coughing. Overloading the stomach may aggravate the cough. A diet of milk or whey may be considered in some instances. Orange juice with glucose may be given freely. Rectal feeding is very unsatisfactory. The chest may be rubbed as a routine with some stimulating liniment.

As regards drugs, there is no specific, although quinine or euquinine in large doses have been recommended. During the catarrhal stage simple expectorant mixtures are sufficient, and later the paroxysms may be modified by such sedatives as bromide, belladonna, phenazone, bromoform, chloral, paregoric and heroin, all of which have their advocates. Perhaps belladonna in increasing doses (2 or 3 minims four-hourly cautiously increased until the pupils are widely dilated) and phenazone are the most generally useful; the latter may be given to a child in doses of 1 or 2 grains with small doses of potassium iodide and expectorants every 4 or 6 hours. Remarkable amelioration of the cough and vomiting may be effected by the use of repeated heavy doses of sodium bicarbonate, the urine being made and kept fully alkaline. It is claimed that intramuscular injections of ether in doses of 1 or 2 c.c. given every 2 days reduce the number of paroxysms. Vaccine treatment with the Bordet-Gengou bacillus is still on its trial. Its prophylactic is greater than its curative value. Attention should be paid to the condition of the nose and throat, and adenoids removed as soon as possible, since they tend to maintain the cough. During convalescence, tonics and a change to the seaside are advisable.

Complications should be treated on general lines. Obstinate vomiting needs careful feeding, and hydrochloride of cocaine in quarter-grain doses 3 times a day, or intramuscular injections of soluble phenobarbitone (gardenal sodium, luminal sodium). Gastric lavage with 0·6 per cent. solution of sodium bicarbonate may help. Asphyxial attacks may be treated by pushing forward the lower jaw and applying artificial respiration. Inhalation of CO_2 is said to be of good effect. Intubation has been practised in some very severe cases. Convulsions call for the mustard-bath or hot pack, with chloral and bromide by the rectum, or an enema of paraldehyde in olive oil. A whiff of chloroform may give relief, and sometimes lumbar puncture with free escape of cerebro-spinal fluid is effective. In broncho-pneumonia sulphonamides may prove effective.

The injection of the serum of convalescents, on the same lines as in measles and in similar doses (*q.v.*), has been advocated as a prophylactic but has proved disappointing.

Although the infectivity of the paroxysmal stage, especially of its latter part, is problematical, patients should be isolated for 5 weeks from the commencement of the whoop, provided the paroxysmal cough and whoop have ceased for a fortnight; or, better, until the infecting organism has disappeared, which may occur after 3 weeks of illness, or a week or two later. The quarantine period for non-immune contacts is 21 days. Disinfection of rooms and clothing is desirable.

CHARLES R. BOX.

BACILLARY DYSENTERY

Definition.—An acute inflammation of the colon sometimes culminating in coagulation necrosis of the mucosa, caused by specific dysentery bacilli and characterised clinically in the acute stages by fever and frequent, small, mucoid, muco-sanguineous, or muco-purulent stools associated with tenesmus and griping.

Ætiology.—No country is exempt, and natives and Europeans of all ages and both sexes are susceptible. Overcrowding, intercurrent disease, deficient dietary, and malnutrition predispose. Even in Europe Flexner or Sonne dysentery bacilli cause epidemics in military barracks, prisons and asylums, and along with Morgan's bacillus No. 1 are responsible for certain outbreaks of summer diarrhœa in children. Dysentery is prevalent in the tropics, especially during the early summer, rainy season, and autumn months, and is spread by fæcal contamination of food or water, either directly from an infected individual or indirectly by the house fly.

Dysentery occurring in epidemic form is always of bacillary origin. Boyd, who has recently reclassified the organisms causing bacillary dysentery, recognises two non-mannitol fermenting bacilli, *B. dysenteriæ* Shiga and *B. dysenteriæ* Schmitz. Of the mannitol fermenting dysentery bacilli there is *B. dysenteriæ* Sonne, which is a late lactose fermentor, and two groups of non-lactose fermenting organisms which include six types of *B. dysenteriæ* Flexner, *i.e.* I, II, III, IV, V and VI, and three types of *B. dysenteriæ* Boyd, *i.e.* I, II and III. The latter types have been found in India, and probably have a much wider geographical distribution.

Pathology.—The large intestine is the site of an acute inflammatory reaction, especially involving the sigmoid flexure, rectum, and cæcum, and in fulminating Shiga cases the mucosa may be converted into a greyish-white or greenish gangrenous membrane. Rarely the ileum is involved. Initially there is redness, injection of vessels, hæmorrhages and muco-purulent exudation; the mucosa becomes infiltrated with fibrin and in severe cases coagulation necrosis results. Localised exfoliation leads to multiple superficial ulcers, often situated transversely on the mucosal folds and separated by congested, red, œdematous mucous membrane. Generally, healing takes place without scarring and recovery is complete. Occasionally chronic dysentery occurs, and then there is considerable thickening and rigidity of the bowel wall with decrease in its lumen. Ulcers may be found, but more

frequently a chronic granular proctitis and colitis, especially involving the distal portion of the gut, result.

Symptoms.—The clinical features vary with the resistance of the patient and the type of invading organism, Sonne infections being often mild, Shiga infections severe. Flexner infections vary in severity but may be rapidly fatal in infants in whom frequent greenish fluid stools are passed containing typical cytological exudate. Toxæmia and dehydration play an important rôle in the clinical picture. Catarrhal, acute, and fulminating types are encountered, as well as entero-dysentery and chronic dysentery. The incubation period is 1 to 7 days, and in acute cases the onset is generally sudden, with fever, possibly preceded by a chill. Nausea, retching, vomiting, and headache are common. Colicky abdominal pain occurs, and there are frequent, small dysenteric stools associated with straining and tenesmus due to sphincteric spasm. The bowels may be opened from five to fifty times daily. As toxæmia increases the cheeks become flushed, the expression anxious, the temperature higher, the pulse more rapid and the tongue coated and yellow. Restlessness, mental confusion, and even delirium may ensue. Dehydration produces an increase in the nervous symptoms, associated with thirst, pinching of the features, sunken eyes, dry brown tongue, decrease in urinary secretion, increase in blood urea, collapse of the peripheral veins, and in infants depressed fontanelles. If acidosis develops the breathing becomes rapid, deep and often irregular. The severest cases may die in a state of collapse with subnormal temperature and cold, blue extremities. Mild catarrhal cases may show neither fever nor any serious indisposition, mild transient diarrhœa with brown fluid stools being the only sign. In the ordinary acute cases the stools rapidly lose their fæculent character and consist of odourless, gelatinous mucus admixed with bright red blood; later they become muco-purulent, and as recovery ensues bile-stained fæcal matter reappears. In the early stages the abdominal muscles may be held rigid, but later the contracted sigmoid may be palpated; localised pain and tenderness are infrequent owing to the absence of peritoneal involvement. The temperature, at first remittent, may become intermittent later, but with appropriate treatment it generally subsides in 1 to 2 weeks. Persistent fever means persistent infection and calls for rigorous treatment.

Entero-dysentery is associated with involvement of the terminal ileum, and if, as rarely happens, the rectum and sigmoid escape, tenesmus may be absent and the mucoid stools less typically dysenteric than usual. The onset is sudden, vomiting is severe, toxic features are marked, there is a high temperature, the mouth and tongue are covered with sordes, and a typhoidal state develops. In the worst cases watery, choleraic-like stools appear, and the patient may die early with collapse symptoms and a subnormal temperature.

Complications and Sequelæ.—Dysentery bacilli do not penetrate deeply or invade the blood stream, and local complications, such as perforation and stricture, are not met with. Joint and eye complications are attributable to dysentery toxins, and filtrates of Shiga cultures produce similar lesions when injected into animals. Acute conjunctivitis, irido-cyclitis and iritis may occur, while generalised peri-arthritis and effusions into the joints are not uncommon, especially in convalescence from Shiga infections; their duration is variable, but, though arthritis and fever may persist for several weeks or even months, permanent deformity is rare. Neuritis, terminal intussuscep-

tion, especially in children, and parotitis and broncho-pneumonia due to secondary coccal infection, may be encountered. Colonic dysfunction following acute dysentery may take the form of constipation in some cases, while in others post-dysenteric diarrhœa or looseness of the bowels due to an " irritable colon " is found : the latter is distinguished from chronic dysentery by an absence of cellular exudate and the negative sigmoidoscopic picture.

Course.—Fulminating Shiga cases may die rapidly of toxæmia and dehydration, but with appropriate treatment the temperature generally becomes normal in less than two weeks. The natural tendency in all types of dysentery is toward complete recovery, the bowel being restored to a normal condition. Rarely chronic dysentery develops.

Chronic Dysentery.—There is a history of typical acute dysentery, often inadequately treated, from which the patient has never really completely recovered. The stools remain more frequent than usual, are foul-smelling, and contain mucus, muco-pus or blood. During exacerbations fever may recur ; such patients become miserable and emaciated ; in some instances they develop anæmia, œdema of the lower limbs, and are liable to succumb from intercurrent disease. The abdomen is scaphoid, and the spastic, thickened, descending colon palpable. Dysentery bacilli are isolated with difficulty, even during exacerbations, and Cunningham was only successful in finding them in 26·7 per cent. of his Indian cases.

Diagnosis.—The clinical history and physical examination of the patient generally suggest the diagnosis, while the more acute onset, severer pyrexia, greater urgency of the bowel symptoms, and the character of the mucoid stools containing bright red blood, help to differentiate it from amœbic dysentery. Immediate microscopic examination will show an absence of *Entamœba histolytica*, a predominance of polymorphonuclear leucocytes, and frequently the presence of non-motile macrophage cells which must not be confused with amœba. Stools for culture must contain mucoid exudate, be absolutely fresh, uncontaminated by urine and antiseptic, and these, if examined in the first few days of illness, yield a high proportion of positive results. Treatment, however, should never be delayed pending cultural findings in a severe case.

Sigmoidoscopy is indispensable in the diagnosis of chronic dysentery. During the acute stages this examination is rarely indicated, and the slightest pressure of the instrument on the inflamed mucosa causes bleeding. If, however, the bowel be examined at that time uniformly diffuse reddening and hyperæmia of the mucosa associated with blood-stained mucus will be found, while in severe cases the greenish-white necrotic membrane is diagnostic. Later, as the membrane separates, shallow, serpiginous ulcers may be observed, located transversely on the mucosal folds, and surrounded by congested, red, œdematous mucous membrane. In chronic dysentery these ulcers may persist, but more commonly the mucosa, which is largely replaced by granulation tissue, shows a red, hyperæmic, granular surface, bleeding readily on instrumentation, which is rendered more difficult by the thickened, rigid, spastic condition of the bowel wall.

Prognosis.—Dysentery, particularly Shiga infection, is a serious disease which demands prompt treatment, and in some epidemics the mortality rate is very high. Infants and young children, the aged, and people who are semi-starved or suffering from intercurrent disease, do badly.

Treatment.—PROPHYLACTIC.—As the disease is spread by water and food, contaminated either directly from a patient or healthy carrier or indirectly by flies, prophylactic measures similar to those adopted in enteric fever are indicated. Unfortunately no satisfactory prophylactic vaccine is available.

CURATIVE.—Treatment is directed towards conserving the energy of the patient, resting the bowel by a low residue dietary, relieving intestinal and systemic toxæmia and dehydration. Rest in bed is essential, and if a bed pan proves too exhausting the buttocks should be well padded with tow. Special attention should be directed to the hygiene of the mouth and to preventing bed sores. *Diet*: Warm feeds (5 to 10 oz.) should be given two-hourly. Only water is permitted for the first day, followed by albumin and barley water, expressed meat juice, clear soups, and jellies. Later, sprulac, arrowroot and sago pudding are allowed. Lactose is useful. Milk is not well borne and alcohol is contra-indicated. *Aperients*: a preliminary dose of castor oil (min. 240) with tinct. opii. min. 15 is given, followed by sodium sulphate (gr. 60),every two to three hours until the stools lose their dysenteric character. Enemata of 1 per cent. saline or 1·5 per cent. sodium bicarbonate (2 pints) are also useful in eliminating toxic material. *Anti-dysenteric serum* is only of value early in the disease, and in severe Shiga infections it should be immediately injected intravenously. A potent monovalent anti-Shiga serum should be used, but the optimum dosage expressed in international units has not yet been determined. Bacteriophage treatment has been disappointing. Dehydration is treated by intravenous injection of Rogers' hypertonic saline, normal saline, or 5 per cent. dextrose in physiological saline (1 to 2 pints). Adrenaline (0·5 c.c. of 1/1000 solution) may be added in cases of collapse. *Symptomatic treatment*: griping and tenesmus may be relieved by hot fomentations, turpentine stupes, morphine suppositories, and starch and opium enemata; animal charcoal and kaolin may be useful for gaseous distension. Complications are treated as they arise.

For chronic bacillary cases treatment is often unsatisfactory. A high calorie, high vitamin, low residue diet is advisable, and autogenous streptococcal vaccines may be tried. Rectal lavage with saline, sodium bicarbonate and chiniofon (quinoxyl, yatren) (1/40), silver protein (1/500), potassium permanganate (1/5000), and eusol may prove useful. Alternatively a 5 per cent. suspension of bismuth subgallate in 4–8 oz. of olive oil may be injected daily. Iron and whole liver may be used for the anæmia, and blood transfusion is sometimes most helpful. As a last resort, appendicostomy, cæcostomy, or even ileostomy, may be advisable in intractable cases; lavage with antiseptic solutions is thus permitted, while, in addition, the last two operations rest the large bowel and so aid healing.

For *Amœbic Dysentery*, see p. 264.

CHOLERA

Definition.—A specific disease due to Koch's comma vibrio, characterised clinically by violent vomiting, painless diarrhœa with copious rice-water stools, dehydration, cramps and urinary suppression.

Ætiology.—Cholera exists endemically in certain far Eastern countries, and especially in India, where Rogers has demonstrated three main endemic

foci from which epidemics spread in the spring and summer through movements of pilgrims who acquire the disease from infected water. Deficient rainfall results in scanty and bad water supplies, and generally precedes epidemics in India. Herding of people in famine camps also favours outbreaks. Occasionally cholera has reached Europe. People of different race, sex and age are all susceptible. The disease itself is generally water-borne, and is caused by the *Vibrio comma* described by Koch (1883). Carriers, who pass vibrios in the stools, need not necessarily have had clinical cholera. Flies also disseminate the disease by contaminating food, milk, etc., with infected fæces. Cholera vibrios occur in great numbers in the rice-water stools, but disappear in over 90 per cent. of patients within 10 days. Phage is said to be absent from the stools of the most virulent cases, and present in mild and convalescent cases. It is also claimed that bacteriophage may convert virulent highly agglutinable vibrios into non-agglutinable ones.

Pathology.—After death rigor mortis sets in early, and a post-mortem rise of temperature is common; the blood is thick and tarry. The small intestines are collapsed and shrunken, the mucosa is denuded of its epithelial lining, congested, perhaps hæmorrhagic, and the lymphoid follicles enlarged. The stomach and liver are congested, and the gall-bladder distended with viscid, thick bile, difficult to expel—hence absence of bile in the intestine. The kidneys show swelling, congestion and ecchymoses, the spleen is small and shrunken, and the lungs collapsed and dry. The comma vibrio is readily isolated from the contents of the small intestine and occasionally from the urine, gall-bladder and lungs.

As a result of denudation of intestinal epithelium fluid pours out from the blood vessels into the lumen of the bowel, and cholera endotoxins are absorbed into the circulation. This toxæmia and fluid loss underlie the pathological findings and clinical picture. Diarrhœa and vomiting lead to chloride depletion, to decrease in blood volume with increased viscosity of the blood, and to tissue dehydration. Biochemical investigations show reduced blood chloride, diminished plasma alkalinity, phosphate retention and increased blood urea. A polycythæmia of 6 to 8 million red corpuscles per c.mm. and a leucocytosis of from 15,000–20,000 per c.mm. are found; hæmatocrit estimations have shown an average loss in serum of 35 per cent. in mild and 64 per cent. in severe cases. Finally the weakened heart may prove incapable of pumping the viscid blood through the damaged kidneys and anuria may result.

Symptoms.—The incubation period is 2 to 5 days. Castellani and Chalmers describe 5 clinical types. (1) *Ambulatory* cases. (2) *Choleraic diarrhœa.* (3) *Cholerine*: the patient suddenly develops severe abdominal pains, passes numerous fæculent motions, then typical rice-water stools followed by rapid recovery. (4) *Cholera sicca*: the patient becomes rapidly collapsed and dies before the typical gastro-intestinal features develop. (5) *Cholera gravis*: typical cholera, constituting 95 per cent. of the cases in most epidemics. When cholera is prevalent the only safe rule is to treat every case of diarrhœa as suspect until proved otherwise. Laboratory confirmation in all atypical cases should be sought. Three more or less well-defined stages are described. (1) *The preliminary diarrhœa*: In this stage—infrequent in Indian epidemics—colicky abdominal pain, looseness of the bowels, headache, vomiting and mental depression may be present for 24 hours.

(2) *The collapse stage*: Once diarrhœa has really started, all fæcal matter rapidly disappears, to be replaced by copious, colourless, rice-water stools containing flakes of epithelium. Watery vomiting also occurs and several quarts of fluid may be lost in a few hours. Cramps, starting in the hands and feet, now appear and soon involve the extremities. Thirst, restlessness and collapse become extreme, the skin is cold, blue and wrinkled, and the face pinched. The voice becomes husky, the respiration rapid, the temperature subnormal, the blood pressure markedly lowered (systolic 55–70 mm.), the peripheral veins depleted and collapsed and the pulse imperceptible. The urine is diminished, contains albumin and casts, and uræmia with suppression and acidosis may follow. Collapse is extreme and only prompt treatment can save the patient. (3) *Period of reaction*: With recovery, the temperature rises, the heart's action and blood pressure improve, the urine increases, diarrhœa decreases and abdominal pain disappears. In less favourable cases, especially where the collapse stage has been prolonged, the circulatory recovery may not be sufficient to restore renal function and fatal uræmia results. Or again, the improved circulation may lead to an overwhelming absorption of cholera toxin from the damaged gut with hyperpyrexia and death.

Complications and Sequelæ.—Cardiac failure in convalescence, persistent cramps, broncho-pneumonia, enteritis, nephritis and cholecystitis may require special medical treatment; parotitis and abscesses need early surgical incision. Abortion and premature delivery are not infrequent, and formerly, before dehydration could be effectively treated, sloughing of the cornea and gangrene of the toes, fingers, penis and scrotum were encountered (Rogers).

Diagnosis.—During an epidemic little difficulty arises, but in atypical and sporadic cases the diagnosis will largely depend on a positive culture. Cholera nostras of temperate climates, the choleraic forms of malaria and dysentery, ptomaine, arsenic and perchloride of mercury poisoning have all to be differentiated.

Prognosis.—The mortality rate has varied in different epidemics from 30 to 80 per cent., being most fatal at the start. Modern treatment has reduced it to about 20 per cent. Over 90 per cent. of cases admitted with a blood pressure above 70 mm. recover. Young children, pregnant women, aged and debilitated people, alcoholics and chronic nephritics do badly. A severe and prolonged collapse stage, uræmic symptoms and hyperpyrexia are unfavourable, but with modern treatment these can often be avoided.

Treatment.—PROPHYLACTIC.—During epidemics cholera vaccine is valuable, affording temporary immunity (6 months). When feasible 1,000,000 dead vibrios in 1 c.c. are inoculated, and a week later this dose is doubled. Unboiled milk and water and uncooked foods, salads and raw fruit must be avoided. Wells should be disinfected immediately an outbreak occurs. Houses should be fly-proof, food covered, and drinking vessels and eating utensils cleaned in boiling water and dried by heat. The value of cholera bacteriophage, both in prevention and treatment, is uncertain. Many different types of phage have been isolated, but no unanimity of opinion has yet been reached.

CURATIVE.—The patient is kept strictly in bed and practically starved for the first few days, but water with or without glucose and barley water are freely given. Efforts may be made to destroy cholera toxin by calcium

permanganate (grs. 2 every ½ hour for 8 doses, then half-hourly), and large doses of kaolin *per os*. The Japanese claim to have used cholera antiserum with benefit. Essentially treatment consists, as Rogers points out, in replacing fluids and salts lost from the blood by appropriate intravenous injections whenever a rise in the specific gravity of the blood above the normal 1056–1058 occurs. A blood pressure below 70 mm., especially if associated with cyanosis, restlessness, cramps and cold extremities, also necessitates transfusion. Rogers advocates two solutions: (*a*) Hypertonic saline (sodium chloride, 120 grs.; calcium chloride, 4 grs.; water, 1 pint) for reinforcing blood volume and chloride loss, and (*b*) an alkaline solution (sodium bicarbonate, 180 grs.; sodium chloride, 90 grs.; water, 1 pint) to counteract acidosis and uræmia. More recently physiological saline, 0·9 per cent., has yielded excellent results. During the *collapse* stage 1 pint of (*b*) is first given and the total quantity as estimated from the specific gravity is made up with Rogers' hypertonic saline solution. Thus a specific gravity of 1063–1064 calls for three pints, and between 1065–1070 for 4 to 6 pints, the aim being to keep the figure below 1060. Injections must be repeated as often as the specific gravity of the blood rises to or above 1063, or the blood pressure falls to 70 mm. As much as 31 pints of saline has been given in the course of 4 days, with recovery. If the rectal temperature is elevated, the temperature of the injected fluid should not exceed 80° F. (room temperature in the tropics) to avoid hyperpyrexia. In the *reaction* stage cold sponging is advisable whenever the temperature exceeds 103° F., and while the blood pressure remains below 100 mm. pituitary (posterior lobe) extract (1 c.c. t.i.d.) is useful. Threatened uræmia is treated by dry cupping, alkaline solution per rectum, and by injections of 5 to 10 per cent. dextrose intravenously. Complications are dealt with as they arise. As the patient improves farinaceous foods are allowed, but proteins and extractives must be withheld until renal function is quite normal.

LEPROSY

Definition.—Leprosy is a chronic bacillary disease of low infectivity peculiar to man, caused by the *Mycobacterium lepræ*, and associated with characteristic lesions involving the skin and mucous membranes (nodular type), and the nerves (anæsthetic type). Infection, however, may remain latent and clinical manifestations never appear.

Ætiology.—The disease has a widespread geographical distribution, occurring in Egypt, Asia, Africa, West Indies and the Pacific Islands, etc. It is not hereditary, and individuals of any age, sex and race may be attacked. Children are more susceptible than adults. The *Mycobacterium lepræ* was discovered by Hansen in 1874; it is a non-motile, acid-fast bacillus occurring in large clumps in skin lepromata, septal ulcers and nasal mucus, and has never been cultivated with certainty. The mode of spread is unknown, but intimate contact with lepers is essential; a history of attendance on lepers, of living in the same house, sleeping in the same bed, or sexual connection is frequently obtained. Only 3 per cent. of people, however, living with lepers develop the disease.

Pathology.—Leprosy bacilli spread through the lymphatics of the corium and subcutaneous tissues, producing granulomata of the skin and infection

of lymph glands; the nasal and buccal mucous membrane, the eye, larynx and internal organs, such as the liver, lungs and testicles, may be similarly involved and bacilli found. The nerves may swell, turn a reddish-grey colour, and undergo an axonal degeneration; scanty bacilli may be demonstrated in the endo- and perineurium. Paralysis, muscular atrophy and deformity follow.

Symptoms.—There are three main types of the disease—(1) nodular or cutaneous leprosy; (2) anæsthetic, neural or nerve leprosy; (3) mixed leprosy. The incubation period is uncertain, being 1 to 5 years in most cases, though occasionally persons develop it a few months after coming into an infected area. Often bacilli remain latent for years, and intercurrent disease may be necessary to precipitate clinical leprosy.

1. Nodular or Cutaneous Leprosy.—This is the low resistant type, in which there is gross infection of both skin and nerves; the neural signs are mild, since the invading organisms fail to elicit any marked response from nerve tissue (Muir). Prodromata, which are marked, include leprotic fever, rigors, sweating, progressive weakness, diarrhœa, alternating dryness and hypersecretion of the nasal mucosa and epistaxis. The first positive evidence is the primary exanthem, involving especially the face, buttocks, legs or arms, commencing as a slightly raised erythematous macule which later shows dissociation of sensation and absence of sweating; it may disappear, leaving some brownish discoloration, but soon fever recurs with a fresh eruption, and bacilli may be found in the blood. After one or two recurrences reddish-brown elastic nodules appear, often at the site of the old macular rash, and these may become more generalised. Only the dorsal surfaces of the hands and feet are affected. The face acquires a leonine aspect from the enlarged nose, lobes of the ear and pendulous cheeks. The hair is often lost, especially on the outer third of the eyebrows, the nipples become prominent, the breasts may hypertrophy, and the mucous membrane of the nose, pharynx and larynx may be affected. Leprotic nodules often involve the cornea and iris. The further history varies; the nodules may remain stationary, disappear or break down and suppurate. Ulcers may form on the eye, causing blindness, and the larynx and pharynx may be destroyed.

2. Anæsthetic Leprosy.—This is a highly resistant type, in which the infection of skin and nerves is less, yet the neural signs are more prominent since the reaction in nerve tissue is more marked (Muir). Prodromata consist of mental depression, chilliness and malaise with neuralgic pains and paræsthesias, involving the ulnar, peroneal and facial nerves. Numbness of the hands and feet, anæsthesia of ulnar distribution, and maculæ, giving rise to flat, anæsthetic patches resembling ringworm may be the first indications. These anæsthetic patches may commence as erythematous or pigmented or depigmented areas and ultimately become dry and hairless. A quiescent stage may now set in until definite nerve lesions appear. Demonstrable fusiform enlargement, especially of the ulnar and great auricular nerves may develop, and wasting of the hypothenar eminence associated with contraction of the third and fourth fingers is often seen. Muscular palsies and trophic lesions of the skin, nails and bones, including perforating ulcers, are common, and atrophies and contractures like claw hand may ensue. Necrosis or interstitial absorption of the small bones occur, and fingers and

toes may disappear. The fifth and seventh cranial nerves are sometimes attacked, and ectropion of the lower lid, followed by corneal ulceration, is common.

3. MIXED LEPROSY.—Many cases ultimately become mixed in type, the nodular and nervous features either developing together or following one another. Tuberculoid leprosy—so called owing to its histological resemblance to tuberculosis—is encountered in patients with a high resistance. The lesions consist of raised plaques or of macules with raised margins: anæsthesia is well marked, and the nerve branch supplying the area is often thickened.

Diagnosis.—Clumps of lepra bacilli which have to be distinguished from tubercle can often be demonstrated in nasal mucus, in scrapings obtained from nasal ulcers using a speculum, and in the serous exudate from granulomata of the skin. The "snip method" of removing a small piece of skin with curved scissors, especially from the lobe of the ear, and making smears from its under-surface, is valuable. Gland puncture may also reveal bacilli. In pure nerve cases they can rarely be found unless portions of the nerves be examined. The differential diagnosis includes in nodular leprosy, lupus vulgaris, skin tuberculosis, syphilis and yaws; and in the anæsthetic type, syringomyelia, Morvan's disease, progressive muscular atrophy, peripheral neuritis, cervical rib, ainhum, scleroderma, and Raynaud's disease.

Prognosis.—This is by no means good in more advanced cases, though with earlier diagnosis and modern treatment the disease may be arrested, the expectancy of life increased and cases sometimes cured. Muir states that if the patient can tolerate maximal treatment and maintain a sedimentation rate below 10 a good prognosis can generally be given. Nodular leprosy is particularly prone to such complications as tuberculosis, renal disease and pneumonia, and laryngeal and visceral involvement are serious.

Treatment.—PROPHYLACTIC.—Lepers must be excluded from acting as cooks, waiters, etc., and segregation properly and humanely carried out is best for all parties concerned. Contacts who have lived in the same houses as lepers should be bacteriologically examined every few months for at least 5 years.

CURATIVE.—As in tuberculosis, the first essential is to increase the general resistance of the patient by good food, fresh air, regulated exercise, and to eradicate intercurrent diseases such as ancylostomiasis, malaria, etc. The confidence and active co-operation of the patient are essential. According to Muir the erythrocyte-sedimentation test affords a valuable index to the patient's resistance, slow sedimentation being favourable. Only when the resistance is high, and the general state of health satisfactory, should special drugs be used with the object of clearing up lepromata, otherwise lepra reactions, with increase in the local lesions, fever and bacillæmia in nodular leprosy and agonising pain in nerve cases, may develop. Too large and too frequent treatments with special drugs are dangerous, the aim being to avoid lepra reactions and to keep the health of the patient at the highest level. Special drugs: the oils of the hydnocarpus and chaulmoogra group have been in use for centuries. Chaulmoogra oil (oleum chaulmoograe) is expressed from the fresh ripe seeds of *Hydnocarpus Kurzii* (King N.O. Bixiniæ), that of hydnocarpus from *Hydnocarpus Wightiana* and *H. anthelmintica*. The crude oil is given by the mouth in 10 minim doses t.i.d., being gradually increased to 60 to 120 mins. per day. Intramuscular injections may be given,

but penetration of a vein may lead to a fatal fat embolism. Antileprol, a mixture of the ethyl esters of the various unsaturated acids of chaulmoogra, is given in capsules, each containing 1 gram, the dosage being 1 to 3 grams daily after meals. McDonald and Dean have used weekly intramuscular injections of Moogrol (ethyl chaulmoograte), beginning with 1 c.c. and increasing by 1 c.c. every third injection up to a total of 6 c.c. Alepol (sodium hydnocarpate), 1 to 5 c.c. of a 3 per cent. solution, can be given subcutaneously or intramuscularly without pain; for intravenous injections a 1 per cent. solution is used. The latest treatment advocated by Muir consists of the intradermal injection of the skin lesions with sterilised *H. Wightiana* oil, which is heated to 55° C. before use to reduce its viscosity; the injection is made with a short guarded needle inserted at an acute angle for 2 or 3 mm. The dosage varies, according to the tolerance of the patient, from 0·5 to 5·0 c.c. once or twice a week. From 0·03 to 0·06 c.c. is injected at each puncture, and some 80 to 100 punctures are required to inject 5 c.c. Six months may be necessary to infiltrate once all the affected skin, while another disadvantage is the pain it may produce. Hydnocarpus oil injected intradermally is stated to act as a local irritant stimulating phagocytosis and possibly antibody reaction from the absorption of lepromatous material, while protein shock effects may also be so induced. Whatever its action, the dosage must be carefully graded and only given when resistance is high.

Any erythematous or raised appearances of the skin or thickened and tender nerves indicate activity of the disease, and cases should be free from *Myco. leprœ* for at least 2 years before discharge; even then it is not possible to say whether the condition is really cured or merely arrested, for leprosy is notoriously a disease of remissions.

Lepra reaction should be treated with diaphoretics such as aspirin, phenacetin, hot drinks, and calcium and alkalis in large doses; small doses of tartar emetic (0·02 to 0·04 gram every second day) and protein shock may be useful; in nerve leprosy the agonising pain may be relieved by adrenaline intramuscularly or ephedrine given orally or by infiltration of the nerve.

Potassium iodide is a dangerous drug, but Muir uses it in the late stages of treatment when the resistance is high and the case has become bacteria-free. Diathermy is of value in subacute and chronic nerve lesions. If the ulnar nerve is bound down to bone—especially at the elbow—freeing adhesions and linear incision of the sheath with or without removal of fibrous tissue may bring relief. Abscesses occurring in the ulnar or other nerves should be incised; drainage is rarely needed.

MELIOIDOSIS

Definition.—A fatal disease, resembling glanders in symptoms and pathology, caused by *Bacillus whitmori*; it has been found in Burma, British Malaya, Cochin China and Ceylon, and is primarily a disease of rodents; the mode of human infection is unknown.

Pathology.—The characteristic lesions are small caseous nodules which sometimes coalesce, forming large honeycombed abscesses in the viscera. The lungs, liver, spleen and, less commonly, the intestines and kidneys may

be implicated, while pustules and bullæ may involve the skin. *B. whitmori* is readily cultivated from these lesions as well as from the blood during the septicæmic stage, but the safety-pin-like bipolar staining organisms are scanty in smears of the pus obtained from the nodules.

Symptoms.—In severe cases the vomiting, purging and collapse may simulate cholera, and death from septicæmia may occur in 3 days; other cases may show remittent and intermittent pyrexia for weeks and months. The clinical picture varies with the organ predominantly attacked, and according to Stanton and Fletcher the clinical types may resemble: (1) plague; (2) broncho-pneumonia; (3) typhoid or malaria; (4) liver abscess; (5) infective endocarditis or general tuberculosis; (6) pyelitis.

Diagnosis.—This is always difficult clinically, and is dependent on the cultivation of the organisms from the blood, sputum, urine, cerebro-spinal fluid or material aspirated from the liver or spleen. Only 10 per cent. of cases have been diagnosed during life.

Treatment.—In man the disease is almost invariably fatal, only two cases having recovered. Autogenous vaccines are worth a trial, but neither vaccines nor anti-sera possess protective power in infected animals.

PLAGUE

Definition.—Plague is primarily a disease of rodents caused by the *Pasteurella pestis*. Transmitted to man by rat fleas, it runs a rapid course with high fever, and a marked tendency to septicæmia and tender enlargement of lymphatic glands. More rarely a pneumonic form develops.

Ætiology.—Plague may occur anywhere; it is more common in sub-tropical regions, but towards the equator tends to die out. High temperatures and a dry atmosphere or high saturation deficiency reduce its incidence in the hot weather in India by killing the flea vector. It spread from Hong-Kong to India, Egypt and Japan in 1896, and 3 years later to the Philippines and South America. People of any race, age or sex are susceptible. The plague bacillus, *Pasteurella pestis*, was isolated by Kitasato and Yersin in 1894. It is readily cultured, and is a short, Gram-negative rod showing bipolar staining. Guinea pigs and other laboratory animals are susceptible. Rat fleas, especially *Xenopsylla cheopis*, which have fed on the blood of infected rodents such as the large grey rat (*Rattus norvegicus*) and the smaller black rat (*Rattus rattus*), desert these animals after death and inoculate man by regurgitating *Past. pestis* during the act of biting and sucking blood. Epidemics in rats invariably precede human epidemics, and an extension of plague to man can be accurately foretold 2 or 3 weeks beforehand from a rising curve of infection in the rat population. Pneumonic plague, on the other hand, is intensely infectious, being directly transmitted by droplet spray infection from person to person. Doctors and nurses often acquired the disease during the Manchurian epidemic.

Pathology.—At the site of entrance, especially in resistant cases, plague bacilli may occasionally produce a primary vesicle. Generally the adjacent chain of lymph glands are acutely inflamed (primary bubo) while others are secondarily involved. Frequently bacilli enter the circulation, producing various degrees of septicæmia and in the most fulminating cases

primary buboes may be absent altogether. The toxic substances elaborated by *Past. pestis* also affect the endothelial lining of the blood vessels, giving rise to congestion and hæmorrhage in the mucous and serous membranes and skin, while the cardiac muscle shows fatty degeneration and the right heart is dilated. On section the primary bubo shows intense congestion and hæmorrhage, with periglandular, gelatinous and hæmorrhagic œdema matting adjacent glands together. More distant glands, secondarily implicated, are congested and greyish-red in colour. Bacilli are numerous in the early stages and also often occur in the spleen and blood. The liver and kidneys are congested, showing cloudy swelling and fatty change, and fibrinous thrombi may be present in the Malpighian tufts. The spleen, which is 2 or 3 times its normal size, is hyperæmic and often hæmorrhagic. The meninges are very congested and hæmorrhages may occur in the brain. Pneumonic plague starts as a broncho-pneumonia, but later may involve the entire lobe; pleural ecchymoses, congestion of the bronchial tree and involvement of the bronchial glands are characteristic.

Symptoms.—The incubation period varies from 2 to 12 days, generally being 3 to 4 days. In severer infections there is a marked tendency toward septicæmia and in the types of pestis major a sudden onset with chill or rigors, irregular high fever, nausea, vomiting, cardiac weakness and great mental prostration is characteristic. Splenomegaly and also hæmorrhagic rashes may occur, hence the ancient synonym "black death." Nine clinical types have been described.

(1) BUBONIC.—Prodromata include backache, pains in the limbs, and mental depression, but generally the onset is abrupt and the constitutional features severe. The blurred speech, reeling gait, and mental dullness may suggest alcoholic intoxication. Examination reveals fever, injected conjunctivæ, rapid soft pulse; the urine contains albumin, and the blood count shows a moderate leucocytosis. On the second or third day a tender primary bubo appears, the affected group of glands (femoral and inguinal = 70 per cent.; axillary = 20 per cent.; submaxillary and cervical=10 per cent.) rapidly swelling to the size of a hen's egg or larger. Pain is severe and suppuration generally occurs during the second week. Death usually eventuates between the third and fifth day; with recovery the symptoms gradually ameliorate, but convalescence tends to be protracted. Secondary broncho-pneumonia may occur, and the sequelæ include sepsis, carbuncles, etc.

(2) SEPTICÆMIC.—The disease is rapidly fatal; there may be splenomegaly and slight general enlargement of lymphatic glands, but no bubo. Frontal headache, fever and vomiting are characteristic, but in the severest cases there may be only a slight rise of temperature. Cutaneous petechiæ and melæna may be noted. The diagnosis is made by a positive blood culture.

(3) PNEUMONIC.—Chill and a rapid rise of temperature occur at onset, followed by headache, dizziness, pains in the limbs, clouding of consciousness, pain and tightness in the chest, with cough and expectoration of a copious, sanguineous, watery sputum teeming with plague bacilli. Dyspnœa with cyanosis, crepitations, and possibly areas of diminished resonance are found. Cardiac failure is common and death almost invariably occurs within 4 days.

(4) INTESTINAL.—A rare form, described by Wilm in the Hong-Kong

epidemic of 1896, as an intestinal disorder with vomiting, incessant purging, and liquid, offensive, bile-stained stools often mixed with blood. Buboes were absent, but pathological lesions were present in the intestine.

(5) CEREBRAL.—In this type, which may resemble cerebral malaria, the mental hebetude characteristic of ordinary bubonic plague progresses to delirium, convulsions and coma. Definite plague meningitis has also been recorded, and may run a chronic course.

(6) CELLULO-CUTANEOUS.—Carbuncles appear having a necrosed and ulcerated centre, with a hard edge surrounded by a red areola, sometimes covered with minute vesicles. The condition is distinguished from coccal carbuncle by the demonstration of *Past. pestis*.

(7) VESICULAR OR VARIOLOID.—In this form the vesicles and pustules may be so abundant as to simulate varicella. *Past. pestis* is readily isolated from the vesicles.

(8) ANGINAL OR TONSILLAR.—Cervical buboes may implicate the tonsils, or violent plague tonsillitis and pharyngitis, with secondary cervical adenitis, may arise from killing vermin with the teeth—a habit of Indians in Ecuador.

(9) ABORTIVE OR AMBULATORY (*Pestis minor*).—Such cases are common in all epidemics: buboes develop and may suppurate or be absorbed without serious indisposition or fever, or the lymph glands may simply swell and become painful, associated with transient headache.

Complications.—Acute bubonic cases may develop plague septicæmia or pneumonia with fatal results, or after the fever has disappeared the local buboes may become indolent and take many weeks to heal. Broncho-pneumonia and septic complications such as subcutaneous abscesses, cellulitis, adenitis and parotitis sometimes ensue.

Diagnosis.—Bubonic plague early in an epidemic may need to be differentiated from climatic bubo, chancroid or syphilitic buboes, rat-bite fever, and possibly tularæmia. Gland puncture reveals bipolar bacilli on culture or in smears, the crucial test being transmission of plague to the white rat by smearing infective material on its skin. In pneumonic plague herpes is absent and the sputum is sanguinolent and watery, not viscid and rusty as in pneumonia: furthermore it is teeming with plague bacilli. Septicæmic plague is diagnosable only by positive hæmo-culture.

Prognosis.—Pneumonic and pure septicæmic plague are practically always fatal. In bubonic plague the mortality rate is much higher in natives (75–80 per cent.) than in Europeans (25–30 per cent.), and axillary buboes are less favourable than inguinal ones. Positive hæmo-culture is of serious significance, and Liston showed that where the bacilli exceed 40 per 1 c.c. of blood, death almost invariably resulted.

Treatment.—PROPHYLACTIC.—This consists essentially in the destruction of rats and fleas, in preventing their coming into contact with man, and in increasing individual resistance by Haffkine's prophylactic vaccine, which gives an immunity lasting 6 to 12 months or more. The building of rat-proof houses and grain stores, rat destruction by poisoning and trapping, fumigation of ships with sulphur dioxide and hydrocyanic gas, and evacuation of infected villages and houses during epidemics are all important measures in controlling the spread of plague.

CURATIVE.—Bed rest, liquid diet, and careful nursing are essential. Specific treatment, with large doses of antiplague serum intravenously during the

first two days has been advocated (Yersin and Lustig), and recently workers at the Haffkine Institute, Bombay, have produced a potent antiplague serum from horses which is yielding promising results. It is given in doses of 20 c.c., and repeated till a total of 60–160 c.c. are administered. Treatment with sulphapyridine (M. and B. 693) and sulphathiazole (M. and B. 760) is under trial; preliminary experiments on animals suggest they may be valuable. The buboes should be treated by hot fomentations, kaolin poultice, or belladonna and glycerin applications with early incision when suppuration occurs. Morphine may be necessary for the pain. Stimulants and cardiac tonics should be used early, and intravenous injections of dextrose may be of value.

UNDULANT FEVER OR BRUCELLIASIS

Synonyms.—Malta or Mediterranean Fever; Abortus Fever.

Definition.—An endemic or epidemic disease characterised clinically by prolonged fever with a tendency to long wavy relapses, splenomegaly, transient painful swellings of the joints, neuralgia and secondary anæmia. In Malta *Brucella melitensis*, conveyed in goat's milk, proved the causative organism, but indistinguishable diseases of widespread geographical distribution may be caused by the bovine and porcine strains of *Br. abortus*.

Ætiology.—Undulant fever of caprine origin is endemic in the Mediterranean basin, in the Red Sea littoral, in South and West Africa, and in the goat-raising regions of Texas, Arizona and New Mexico. In the East it is found in India, Assam, Hong-Kong and China; in the West in the West Indies, Porto Rico, and northern countries of South America. The indigen population sometimes appears to have a certain immunity to the dis ous as in Malta, where the Maltese, prior to the boiling of goats' milk b ease, garrison, were less affected than English soldiers and sailors. All agev the both sexes appear equally susceptible, and in Malta, at least, the ds and proved more prevalent in the dry summer months. isease

Bruce, in 1886, isolated *Br. melitensis* from cases of undulant fever and experimentally reproduced the disease in monkeys. Eighteen years later it was proved that infection was conveyed in goats' milk. The organism causes a bacteriæmia and may be isolated from the blood, bile, fæces, urine and milk. Primarily it is a disease of goats which, while themselves showing few symptoms, may yield a good quality milk containing large numbers of *Br. melitensis*. Other varieties include the bovine and porcine strains of *Br. abortus*, and are only distinguishable by agglutinin-absorption tests. The latter organism, which infects the chorionic cells, causes contagious abortion of swine and cattle, and produces a disease in man indistinguishable from undulant fever; it has been reported from the United States, Europe, Southern Rhodesia, South Africa, etc., is of bovine or porcine origin, and is contracted from cow's milk or contact with carcases, infected animals or their excreta.

Pathology.—The disease is essentially a bacteriæmia and organisms may be isolated from the blood, spleen and lymph glands at autopsy. The spleen is constantly enlarged, averaging about 20 ounces in weight. Sometimes the mesenteric glands appear swollen, but there is no ulceration of

Peyer's patches. The liver, kidneys and pulmonary bases show congestion, and occasionally broncho-pneumonia and glomerular nephritis are found.

Symptoms.—The incubation period is about 14 days, but may last a longer or shorter period. Monkeys develop fever 5 days after subcutaneous inoculation, and 15 days after ingestion of infected material. Five clinical varieties are recognised by Hughes: (1) Ambulatory; (2) Undulant; (3) Intermittent; (4) Continuous; (5) Malignant.

(1) AMBULATORY OR MILD.—In some cases the symptoms are so slight that infected persons go on with their work as usual; in others there are slight fever and minor symptoms which disappear rapidly, serum tests alone indicating infection. Out of 525 dock hands examined by Shaw in Malta, 79 gave positive agglutinin reactions, whilst 9 out of 22 of those specially tested showed the organism either in the blood or urine or both. Such cases constitute human carriers.

(2) UNDULANT OR ORDINARY.—The onset is generally insidious like typhoid, and the symptoms often resemble those seen in other fevers, but the temperature chart is characteristic. Bouts of fever lasting 2 or 3 weeks alternate with periods of remission, so producing the typical undulant fever chart. Illness in the ordinary case lasts 3 to 4 months, the extremes being 3 weeks to several years. The fever is often associated with profuse sweating, lassitude, secondary anæmia, debility and transient painful swelling of the joints resembling rheumatic fever, but not responding to salicylates. Enlargement and tenderness of the spleen and liver also occur, and neuralgic pains, especially involving the intercostal and sciatic nerve, are common. The tongue has a central white fur, and anorexia, flatulence, abdominal discomfort and constipation are often troublesome features. The leucocyte count is generally normal, but there is a relative lymphocytosis; the urine may contain albumin. After running a more or less chronic course, the remissions become more prolonged, the febrile exacerbations less high, and recovery gradually ensues. No patient should be regarded as convalescent, however, until the temperature and pulse have been normal for at least a fortnight and all other symptoms have disappeared. Neuritis, debility and anæmia may persist for a considerable period.

(3) INTERMITTENT TYPE.—There is a swinging temperature resembling benign tertian malaria, a normal morning temperature being succeeded by a sudden afternoon rise to 105° F. or higher, accompanied by chilliness and a definite rigor; by evening the temperature falls again with drenching sweats. The condition is differentiated from malaria by the absence of parasites.

(4) CONTINUOUS TYPE.—Here there is continuous fever for a period of from one to three months.

(5) MALIGNANT TYPE.—The patient is attacked suddenly with high fever, severe generalised pains, diarrhœa and vomiting. Broncho-pneumonia, cardiac weakness and a typhoidal state frequently develop, while hyperpyrexia may percede death.

Complications.—These include bronchitis, broncho-pneumonia, neuritis, parotitis, orchitis in the male and mastitis in the female. Purpura and suppurative osteitis have also been described. Menorrhagia, abortion or premature labour may also result.

Diagnosis.—The differential diagnosis includes the enteric fevers, acute rheumatism, malaria, kala, azar, tuberculosis, subacute bacterial endocarditis, thoracic lymphadenoma associated with the Pel-Ebstein syndrome, amœbic abscess of the liver and occult pyogenic infections. Macroscopic agglutination reactions are of great diagnostic value after the first fortnight of fever, the serum being tested in an ascending series of dilutions (1/25–1/1000) against dead Brucella emulsions. Absorption of agglutinin may be necessary to distinguish infections with *Br. melitensis* and *Br. abortus* respectively. Blood culture in liver infusion broth is often positive for *Br. melitensis*, and the period of examination should extend over a fortnight before reporting the result as negative. *Br. abortus* must be grown in an atmosphere of 10 per cent. carbon dioxide or, better still, 1 c.c. of suspected blood is inoculated into the peritoneal cavity of a guinea-pig, culture from the peritoneal cavity being generally positive in about a week and from the spleen at a later date. Burnet's intradermal test is frequently positive; it is characterised by the development of localised redness and œdema some six hours after inoculation, the reaction lasting 1 to 2 days.

Prognosis.—Mortality rates of from 2 to 9 per cent. have been recorded. Death generally results in malignant cases during the first three weeks of fever. At any time, however, fatal recrudescence may occur, a typhoidal state, broncho-pneumonia, cardiac failure and hyperpyrexia being grave signs. Chronic cases may present great debility, emaciation, anæmia and neuritis.

Treatment.—PROPHYLACTIC.—Laboratory workers should be very careful in handling Brucella cultures for, as in tularæmia, infection is easily acquired. Adequate boiling of goats' milk renders it safe, but its prohibition in endemic centres and the destruction of infected animals are more effective. Cream and cheese may also convey infection. In the case of *B. abortus* the disease may arise from cows' milk or the carcasses or excreta of bovines and porcines.

CURATIVE.—Careful nursing and a nourishing dietary which should include milk puddings, eggs, fish, fruit juice, yeast and other vitamin-containing foods, are desirable. Cool sponging is indicated whenever the temperature exceeds 103° F. Specific therapy is still under trial. Anti-undulant fever serum has been favourably reported on, as has also immune-transfusion in the form of a direct transfusion of 500 c.c. of compatible blood from a recovered case. Autogenous vaccines are of doubtful value. A course of sulphapyridine terminates the fever in some cases, but recurrences are not infrequent. Cures are recorded following T.A.B. vaccine intravenously, commencing with 50 millions and working up to 250 millions, injections being given every fourth day. Various symptoms and complications, such as sleeplessness, headache, arthritis and orchitis, should be treated on general principles as they arise.

BARTONELLOSIS

Two clinical forms of Bartonellosis are now recognised, namely, (1) Oroya fever, in which there is a generalised infection with *Bartonella bacilliformis*; and (2) Verruga peruviana, in which there are local lesions in the skin.

Oroya Fever

Synonyms.—La Maladie de Carrion; Carrion's Disease; Generalised Bartonellosis.

Definition.—An acute infectious disease caused by *Bartonella bacilliformis*, characterised by irregular remittent fever, headache, tenderness over the bones and a severe anæmia of megalocytic type; fatalities are frequent.

Ætiology.—Oroya fever is limited to valleys on the western slopes of the Peruvian Andes between 1800 and 9000 feet. Both sexes are susceptible and children may be attacked. Carrion (1885) inoculated himself from a verruga nodule and died of Oroya fever a month later. Barton (1909) found rod-like organisms in the red cells in this disease; they were also numerous in the endothelial cells of the lymphatic glands. Noguchi (1926) cultured the organism and subsequently experimentally infected monkeys, the susceptible animals developing a condition like Oroya fever, the most resistant ones, lesions of verruga peruviana only. The disease is most prevalent from January to April, when insect life is most plentiful. Transmission is probably by sand-flies of the species *Phlebotomus noguchi* and *P. verrucarum*.

Pathology.—The skin is yellow, the lymphatic glands, liver and spleen are enlarged, and the long bones filled with red marrow. The heart shows fatty degeneration, the liver zonal necrosis, while endothelial cell hyperplasia is common. Petechial hæmorrhages occur in the skin and serous sacs.

Symptoms.—The incubation period is about 3 weeks, the onset being fairly rapid with malaise and headache. Irregular remittent fever somewhat similar to paratyphoid, pains in the joints and tenderness over the long bones are characteristic, while the spleen and lymph glands may be enlarged. Grave anæmia of hæmolytic megalocytic type rapidly develops, in the severe cases the red cells falling as low as 1,000,000 per c.mm. The colour index often exceeds 1·0, and polychromatophilia, poikilocytosis, normoblasts, erythroblasts and even megaloblasts are evident in blood smears. The indirect van den Bergh reaction shows hyperbilirubinæmia. Unlike pernicious anæmia it presents a marked leucocytosis with a shift to the left, myelocytes and meta-myelocytes being present, lymphoblasts, Turck cells and the Reider type of lymphocyte are also common (Monjl and Weiss). Œdema of the legs, cardiac murmurs and retinal hæmorrhages may occur, while hæmorrhagic manifestations of the skin and gums, and coma with subnormal temperature are met with in severe cases. The acute stage of the illness lasts some two weeks, and may either terminate fatally or pass on into the eruptive stage with chilblain-like nodules, *i.e.* verruga peruviana.

Diagnosis.—The rod-shaped bacilli are only demonstrable in the blood smears in severe infections, and Noguchi preferred culturing *Bartonella bacilliformis* for this reason. The limited geographical distribution and the rapid onset of a febrile megalocytic anæmia are important features in diagnosis, but malaria, paratyphoid, rheumatic fever and tuberculosis may need to be differentiated.

Prognosis.—A great variation in the intensity of the infection in different patients is noted. Mild cases recover, but in well-established cases of Oroya fever the mortality rate is from 30 to 40 per cent.

Treatment.—Sand-fly bites should be avoided by sleeping under netting with a 22-inch mesh.

Specific treatment with an arseno-antimony compound, Sdt. 386B, is now available. This drug, introduced by Kikuth, is given intravenously in a dosage of 0·1–0·3 g. on three or more occasions. Bartonella rapidly disappears from the blood, and the anæmia improves. In some cases a total of 5·7 g. was tolerated without untoward effect.

Verruga Peruviana

Synonym.—Localised Bartonellosis.

Definition.—This is the eruptive stage of Oroya fever in which host resistance is high; miliary and nodular lesions may result which show a marked tendency to ulceration and hæmorrhage.

Ætiology.—The disease may be transmitted by local inoculation from monkey to monkey, and Noguchi has successfully cultured *Bartonella bacilliformis* from the local lesions. Only specially susceptible animals show the systemic manifestations associated with Oroya fever.

Pathology.—The pathological lesion is a very vascular, infective granuloma showing a marked tendency to ulceration and hæmorrhage. The endothelial lining of both lymphatics and capillaries proliferates. Plasma cells and fibroblasts appear in an œdematous, delicate reticulum containing numerous blood vessels around which angioblasts undergoing mitosis may accumulate; the late appearances may simulate fibrosarcoma.

Symptoms.—The incubation period varies from 2 to 5 weeks, when rheumatic-like pains develop in the limbs and joints associated with moderate fever which generally subsides within a few days. Subsequently an eruption of tubercles and nodules occurs. The *miliary type* of lesion commences as a red macule which gradually develops into a flat or pedunculated wart-like structure about the size of a small pea; the lesions occur most frequently on the face and extensor surfaces of the arms and legs, but similar ones may involve the mucous membranes of the eyes, nose, pharynx and larynx, giving rise to cough, hoarseness, epistaxis and even sudden death. The *nodular type* of lesion may attain the size of a chestnut; these tumours often ulcerate, forming large, bleeding, fungating masses situated in the flexures of the joints and appearing in successive crops. Little difficulty is experienced in diagnosis and fatal results are rare, though the disease may last 2 to 3 months.

Treatment.—When the nodules ulcerate they should be dressed with antiseptics, and if they undergo necrosis or hæmorrhage severely they may be excised. Intravenous injections of Sdt. 386B, should be administered.

B. DISEASES CERTAINLY, OR ALMOST CERTAINLY, OR POSSIBLY DUE TO FILTRABLE VIRUSES

INTRODUCTION (see pp. 8–10)

THE COMMON COLD

Synonyms.—Acute Coryza ; Cold in the Head.

Definition.—An inflammatory process affecting the upper respiratory tract in which the air sinuses and tubes in connection therewith may also be involved.

Ætiology.—Colds are very common in the damp variable weather of the autumn, winter and spring in temperate climates. Susceptibility to infection tends to diminish with age, yet shows great variation amongst different individuals and even in the same individual under different conditions. Both sporadic and epidemic forms are met with, and infection may spread through a community with great rapidity. Amongst important predisposing causes are frequent changes of atmosphere, as by entering and leaving hot, stuffy, ill-ventilated, crowded rooms ; the presence of a focus of chronic infection in the upper respiratory tract, *e.g.* adenoids, infected tonsils and chronic cranial sinusitis ; structural anomalies which interfere with free ventilation of the nose, *e.g.* deflected septum, and polypi ; and chronic irritation of the mucosa by smoke, dust or chemicals in sprays, etc. Very little is known of the exact pathogenesis, but there would appear to be at least two factors. A filtrable virus seems to be primarily responsible, aided by other organisms which set up a secondary infection, either severally or together. The virus is air borne, and spread is by droplets expelled from the nose and naso-pharynx by sneezing, speaking, coughing, etc. The portal of entry is the nasal or pharyngeal mucosa and, possibly, the conjunctival sac ; infection develops locally via the submucous lymphatics to neighbouring areas, all or one of which may bear the brunt of the inflammation, the resulting clinical picture being an acute rhinitis, sinusitis, pharyngitis, laryngitis or tracheitis. The secondary infection may be by organisms already present as normal inhabitants on the inflamed mucosa, *e.g.* pneumococcus, streptococcus viridans or micrococcus catarrhalis ; or pathogenic bacteria generally conveyed by droplet, *e.g.* hæmophilus influenzæ, streptococcus hæmolyticus, staphylococcus pyogenes. It is impossible to be dogmatic as to which signs and symptoms are consequent on the primary or the secondary infection respectively ; it may be that variations in symptoms and the degree of the accompanying toxæmia in different individuals in the same epidemic are due to variations in the secondary infection. Local infection induces vasodilatation and œdema in the spongy submucous tissues and engorgement of the mucosa, with outpouring of mucoid secretion, which soon becomes muco-purulent in character. The swelling may cause obstruction to the outlet of an air cell, particularly in the ethmoid or sphenoid, or to the duct of the frontal sinus ; absorption of air behind such an obstruction may be responsible for a " vacuum headache," or if

the Eustachian tube is involved to deafness and vertigo; when an air sinus is implicated in the inflammatory process and its opening is obstructed, local pain and "distension headache" are prone to follow.

Clinical Features.—The incubation period varies considerably but is usually between 12 and 48 hours; it would appear to be shortened by chilling of the body or exposure to wet. The first symptom is often a stuffiness in the nose, which is soon accompanied by a pricking sensation and sneezing; a profuse discharge, at first mucoid but which within 12 hours becomes mucopurulent, may lead to excoriation of the anterior nares. Taste and smell are impaired. Pharyngitis and tonsillitis are common, and there may be some follicular exudate on the tonsils. If the inflammation spreads to the larynx, the voice becomes hoarse, and a tracheitis will induce a painful irritating cough which may be paroxysmal, especially at night, and retrosternal soreness. Symptoms are confined in the main to the respiratory tract. Constitutional disturbance is usually slight, though in some epidemics the temperature may reach 102° F. for 48 hours. In such cases pain in the back and limbs, and a sense of exhaustion may be experienced. The catarrh slowly subsides, and the patient is usually free from symptoms in from 4 to 7 days. Immunity is shortlived.

Complications and Sequelæ.—When these arise, they are consequent on the secondary infection. Some suffusion of the conjunctivæ is common. Herpes around the nostrils and on the lips may be extensive during the acute stage. Suppuration in the accessory sinuses or an acute otitis media may occur. Bronchitis, especially in those patients liable to that disease, may flare up and persist for a long time. Broncho-pneumonia is the most serious complication, and not a few cases of pulmonary tuberculosis follow a "neglected cold."

Treatment.—PROPHYLACTIC.—The avoidance of infection in the community is well-nigh impossible, but much may be done by efficient ventilation and fresh air. When knowingly exposed to infection, it is a good rule to keep the mouth shut as far as possible, and on leaving some individuals have faith in taking a pinch of snuff into each nostril. A full dose of quinine is certainly sometimes of value when symptoms threaten: *e.g.* liq. quininæ ammon., min. 120, tinct. opii camph., min. 60, spir. ammon. aromat., min. 60, in half a tumbler of water; which may be repeated in 4 hours if necessary. Stock anti-catarrh vaccine undoubtedly has a prophylactic value in some seasons; though the results of inoculation may appear encouraging through one winter, they may be disappointing the next, or *vice versa*. If inoculation is to be employed in this country it is recommended that four doses ($\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and 1 c.c.) of the St. Mary's Hospital vaccine should be given subcutaneously at weekly intervals during September, followed by 0·5 c.c. once a month throughout the winter. In those patients in whom recrudescence, relapse or repeated re-infection appear to be associated with a chronic inflammatory focus in the upper respiratory tract, that focus should be eliminated by surgical means; in these conditions vaccine therapy is not included in the first line of attack.

Discharge from the nose and throat during the first 48 hours is highly infective; handkerchiefs, pillow-cases and other materials likely to be soiled should be soaked in disinfectant.

GENERAL.—Though isolation is, in theory, admirable both for the pro-

tection of the patient and for limiting the spread of the disease, in practice it can be enforced but seldom. If there is much constitutional disturbance, if the patient suffers from the frailty of old age, or active pulmonary disease, or diabetes mellitus, or subacute nephritis, or heart failure, the common cold must be taken seriously and the patient confined to bed until free from symptoms for 48 hours.

Treatment is entirely symptomatic. In the early stage stuffiness of the nose and throat may be relieved by inhalation for 10 minutes from a jug containing boiling water ¾ pint and cold water ¼ pint (or a pint of boiling water allowed to stand for 7 minutes), tr. benzoini co., min. 60, and menthol grs. 2. This should not be done just before the patient goes out of doors. A solution of 2 per cent. silver nitrate or colloidal silver may be used as a spray. Amphetamine (benzedrine) and ephedrine may give temporary relief to symptoms by shrinking the congested nasal mucosa ; they should not be used to excess. Hoarseness of voice and the retrosternal soreness of tracheitis may be helped by local counter-irritation ; a piece of active mustard plaster the size of half a crown applied to either side over the thyroid cartilage for 20 minutes, or heat in some form, may serve to restore a lost voice. Diaphoresis is encouraged by aspirin, Dover's powder and a hot drink at bedtime. Drugs of the sulphonamide group should not be administered as a routine ; only when a pyogenic complication develops should the appropriate drug be given, and in full dose.

HORDER.
A. E. GOW.

MEASLES

Symptoms.—Morbilli.

Definition.—A specific infectious fever, characterised by catarrh of the respiratory passages, the presence of Koplik's spots on the mucous membrane of the cheeks, a distinctive papular eruption on the skin and a special liability to pulmonary complications.

Ætiology.—Measles is of universal distribution. Both sexes are equally liable. It is extremely infectious, and there is little evidence that natural immunity ever occurs, but a temporary active immunity may be acquired during epidemics without an overt attack. When introduced among unprotected communities it spreads with appalling rapidity to persons of all ages, and causes many deaths. More than half the attacks of measles occur in the first 5 years of life, but there is a temporary passive immunity of the newborn child, possibly due to maternal immunity, gradually waning after the first 3 months, and infants under 6 months rarely take the disease. Early incidence is most pronounced in poor and crowded communities ; among the middle classes it is delayed to school age or later. Seven-eighths of all cases occur in children under 10. When measles occurs in a pregnant woman abortion or premature delivery often results, and the infant may also exhibit the rash, usually in the same stage as the mother (*Congenital Measles*). The disease is endemic in large cities, and cases are numerous from December to March, again increasing in May and June. Epidemics recur every two or three years, and every tenth year an especial incidence is said to be noticeable.

The virus resides in the secretions of the respiratory tract and direct infection is the rule, very intimate contact is not essential. Infectivity may be present 5 days before the appearance of the rash, possibly longer, and then rapidly declines. Only on rare occasions do intermediaries convey the infection, and rooms and fomites do not retain it for more than a short period. There is no evidence incriminating water, milk or other articles of food.

Pathology.—The causal agent is a filter-passer, but has not been positively identified. A small diplococcus, which forms green colonies on blood-agar, isolated by Ruth Tunnicliff, was at one time suspect. The disease has been reproduced in man and monkeys by inoculation with blood, bronchial secretions or tears. The most striking visceral change is broncho-pneumonia. Secondary infections chiefly with hæmolytic streptococci are common. Catarrhal or ulcerative laryngitis may be found. The bronchial glands are inflamed and the lymphoid aggregations of the small intestine may be very conspicuous. Active tuberculous lesions are not uncommon.

Symptoms.—The rash appears on the fourteenth day of infection, sometimes a day earlier or a day later, but it may be delayed in patients who have been injected with the serum of convalescents. This interval is more constant than that which elapses between infection and the first catarrhal symptoms. Reckoning to the onset of fever and catarrh 9 or 10 days usually pass. In some cases the incubation period is slightly febrile and a transitory feverish catarrh with fleeting rash has occurred even a few hours after exposure to infection (Goodall's *illness of infection*). A polynuclear leucocytosis is characteristic of the incubation stage. Slight enlargement of the cervical, inguinal, axillary and other glands may precede the eruption. Koplik's spots on the buccal mucosa may precede the rash by 2 or 3, sometimes by 5, days. Prodromal rashes are not uncommon ; a precocious macular eruption is the commonest, but a punctate scarlatiniform erythema is the most important, since it simulates scarlet fever. It is apt to appear on the second day of invasion. An urticarial rash may also occur.

Invasion.—This is characterised by catarrh of the respiratory tract, fever and the outbreak in the mouth of Koplik's spots. It culminates in the appearance of the skin eruption. Sneezing, irritating cough, watery eyes and conjunctival injection are the early signs. There is chilliness, and the temperature may reach 103° F. by the end of the first day. Photophobia and sharp diarrhœa may occur. In the early stage of invasion slight blotchiness of the skin about the mouth and nose may be evident. The cutaneous rash usually appears on the fourth day, and a deceptive remission of symptoms and fall of temperature sometimes occur just before its outbreak. In some instances laryngeal symptoms are marked during the invasive stage, and give rise to suspicion of diphtheria ; exceptionally, catarrh is insignificant, and an attack of severe simple tonsillitis is simulated.

Koplik's spots are of great importance in the early diagnosis, since they are recognisable some 72 hours before the rash, with the appearance of which they rapidly disappear. They are minute superficial specks of a bluish-white tinge, and show a tendency to aggregate into small clusters or granular patches. Their common site is on the inner aspects of the cheeks, opposite the line of apposition of the molar teeth ; but they may be more widely scattered over the buccal mucous membrane, on the inner surfaces of the

lips, and also on the conjunctivæ. Sometimes they are surrounded by a bright red areola. In addition, the mucous membrane of the mouth becomes congested and dusky, and a decided blotchy enanthema may here precede the cutaneous rash.

Period of eruption.—With the approach of the rash the symptoms become aggravated. The temperature (Fig. 3) rises sharply, it may be to 104° or 105° F. The hurried respiration and slight cyanosis may suggest broncho-pneumonia. Diarrhœa may persist, and sometimes urinary irritation is noticeable. The nasal and conjunctival discharges become more purulent. The eruption makes its first appearance about the brow, behind and below the ears, and in the circumoral region. Rarely, it appears first on other parts, such as the buttocks, thighs or wrists. It spreads rapidly, sometimes after a short hesitation, over the face, neck, trunk and extremities, and is usually fully out on the fifth or sixth day of the attack. Small brownish macules are the first elements, but they soon become papular, and show a tendency to fuse into groups with irregular sinuous outlines. Profuse eruptions may become confluent on the face, neck, back and extensor aspects of the limbs. Petechial hæmorrhages in the rash are not uncommon. The skin is usually moist and exhales a peculiar musty smell. Rarely, it is hot and dry. Itching or burning sensations may accompany the rash. The eruption fades in the order of its appearance, and usually disappears in the course of two or three days; but brownish staining may persist for some time, particularly on the back. A fine branny desquamation speedily follows. At its first appearance, the rash may fail for a time to spread; retrocession is also sometimes observed. A badly developed and retarded rash is characteristic of some severe attacks, and in asphyxial states the rash may be quite cyanotic. As the rash develops, the temperature continues to rise, reaching its maximum with the climax of the attack in from 24 to 48 hours. When the rash begins to fade, the temperature falls more or less abruptly by a crisis which is rather prolonged. The pulse-rate is increased in proportion to the fever, but the respiration is disproportionately rapid. The catarrhal symptoms also reach their greatest intensity at the height of the eruption. Headache, slight delirium, insomnia

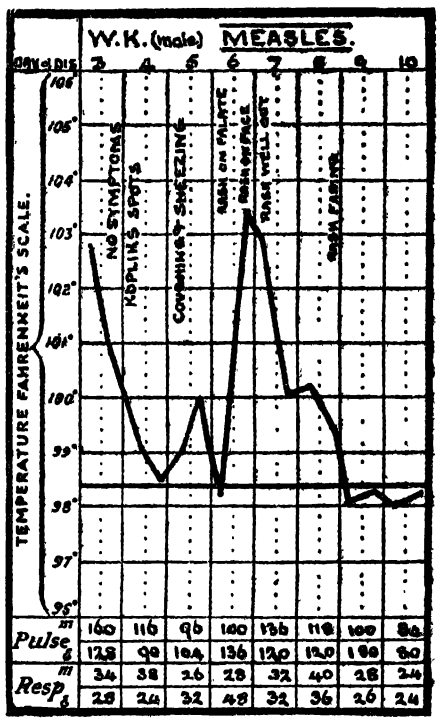

FIG. 3.—Measles. Showing the remission in invasion stage and the abrupt termination.

and a feeling of intense wretchedness are characteristic of this period. The throat may be sore, and the glands at the angle of the jaw tender. The tongue at first is heavily coated, but before long red papillæ are evident, and when peeling is complete a clean, red papillated tongue, very like that of scarlet fever, may often be seen. With the crisis rapid amelioration of all symptoms should occur.

The blood now shows a leucopenia with a high percentage of large lymphocytes. All complications induce a polynuclear leucocytosis.

The urine presents the ordinary febrile characters. Transitory albuminuria may occur. Ehrlich's diazo-reaction is nearly always present, and is most marked when the temperature begins to fall. An acetone reaction is obtained in most cases.

VARIETIES.—Attacks may be mild or severe. Some of the mildest attacks are abortive, the rash failing to appear, and only Koplik's spots giving a clue to the disease. Severe attacks are classified as toxic, pulmonary and hæmorrhagic. The *toxic type* includes those cases in which the patient may succumb during the eruptive period without evident complication. Ill-defined rashes, high fever, muscular tremor, delirium, dyspnœa and circulatory failure are characteristic features. In the *pulmonary type* the infection falls with especial stress upon the lungs. The temperature is high, the respirations rapid and hissing, and the condition suggestive of slow asphyxia. Consolidation of the lungs cannot be detected, but rhonchi are present everywhere, accompanied by fine crepitations. A stuporose condition may precede death or terminal convulsions may arise. The true *hæmorrhagic type* of measles is rare. The patient may bleed from the mucous membranes with hæmorrhages into the skin and subcutaneous tissues. Recovery takes place in some instances. Hæmorrhage *into* the rash has not the same grave significance.

Complications.—These are numerous, but those involving the respiratory tract, the middle ear and the bowel are the most important.

Laryngitis may accompany the onset, develop during the eruption, or appear early in convalescence. Arising in the invasive stage it may simulate laryngeal diphtheria. Laryngitis is more common during the eruptive period, and may persist for some days—it may be complicated by laryngeal ulceration, sometimes by œdema of the glottis; but necrosis of the laryngeal cartilages and abscess formation are rare. Severe laryngitis developing during convalescence should always arouse suspicion of diphtheria.

Bronchitis is often present during the eruptive stage, but broncho-pneumonia is a much more serious complication, and is a common cause of death. Its incidence is favoured by climatic conditions, overcrowding and contact with similar cases. It is generally attributed to secondary pneumococcal or streptococcal infection; but, especially when occurring early in the infection, it is rightly regarded as due to measles itself. This early broncho-pneumonia is associated with a high temperature and considerable toxæmia. It is suffocative in type, and the lung signs are rather those of capillary bronchitis than of consolidation. During the eruptive stage, broncho-pneumonia should be suspected if the temperature fails to fall with subsidence of the rash, and the pulse remains quick and respiration rapid. It may clear up in a week or ten days, but often persists for weeks, or relapses. The temperature chart often shows remarkable daily remissions and exacerbations which may lead to suspicions of tuberculosis. The mortality is serious, since

one-third or one-half of the children attacked are said to die. Feeble infants succumb rapidly, and in those who recover convalescence is protracted. True lobar pneumonia is uncommon. Massive collapse of the lower lobe of a lung has been described; its onset is sudden with intense dyspnœa, cyanosis and cardiac failure. It is distinguished from pneumonia by the feebleness of the breath sounds, upward displacement of the diaphragm and dislocation of the heart towards the affected side. Rarely mediastinal and subcutaneous emphysema have occurred. Effusions into the pleura have been noticed in some epidemics, and empyema may follow. Fibrosis of the lung and bronchiectasis may originate in the broncho-pneumonia of measles.

Pericarditis or endocarditis sometimes develops; and may be associated with chorea. Arthritis with rheumatic pains is sometimes pronounced.

Blepharitis and phlyctenular ulcers of the cornea are common sequels. In cachectic children intense conjunctivitis may arise and lead to ulceration and even perforation of the cornea with destruction of the eye.

The catarrhal stomatitis of measles occasionally persists and becomes ulcerative. A gangrenous form (noma) may attack the lips, cheeks, vulva or other parts. A discoloured patch appears on the mucous membrane and quickly ulcerates, extending both in depth and breadth. A zone of inflammatory induration surrounds the lesion, and a fetid odour is given off. Noma is terribly destructive both to soft parts and bone, and is very fatal. It occurs in debilitated and feeble children, and is attributed to secondary infection. Vincent's spirilla and fusiform bacilli are often present. It is said to be sometimes due to the Klebs-Loeffler bacillus.

Otitis media is frequent. It may be catarrhal or suppurative; the suppurative form is more common in children, and is responsible for much chronic ear disease. Mastoid inflammation may occur, and deafness may result.

Cutaneous eruptions of eczematous, impetiginous or pustular type are common. Sometimes they are widespread, and very resistant to treatment.

Enlargement and suppuration of the cervical glands, entero-colitis and ascites are rarer complications.

Encephalo-myelitis may occur towards the end of the first week, with a course which is either rapidly fatal or tends to spontaneous recovery. Meningeal symptoms or convulsions may signalise its onset. Hemiplegia, aphasia, coma or mental defect are rare. Myelitis, sometimes of the ascending form, has been known to occur; also symptoms suggestive of disseminate sclerosis. Sometimes the cranial nerves are attacked. Paralysis of extra-ocular muscles, papillœdema and optic atrophy have all been encountered. The peroneal type of muscular atrophy may follow measles.

Measles especially favours the development of tuberculosis hitherto latent in the bronchial glands or elsewhere. Caseous broncho-pneumonia, miliary tuberculosis of the lungs, or general tuberculosis with meningitis may follow measles immediately or occur after a quiescent period. Measles often occurs in close association with whooping-cough, diphtheria and scarlet fever.

Relapse in measles is rare. Second attacks, although uncommon, undoubtedly occur, and some unfortunate individuals never appear to

acquire any lasting immunity. Fourth, and even seventh, attacks are known.

Diagnosis.—In the prodromal stage, measles may be mistaken for ordinary naso-pharyngeal catarrh. If laryngitis is pronounced, and the child croupy, diphtheria may be simulated. Mastoid operations, operations on the tonsils and even on the appendix sometimes are performed precipitately before the true nature of the infection is recognised. Febrile symptoms and loss of weight during the incubation stage may be erroneously attributed to tuberculous infection. The prodromal scarlatiniform rash may lead to confusion with scarlet fever. These errors may be avoided by bearing in mind the possibility of measles, inquiring for possible exposure to infection, and particularly by a careful search for Koplik's spots, and shottiness of the posterior cervical glands. The pre-eruptive fall of temperature and recession of the catarrhal symptoms before the appearance of the rash should be borne in mind, and not lead to premature relaxation of precautionary isolation.

In the eruptive stage, the fevers with which measles may be confused are rubella, small-pox, and perhaps typhus.

Rubella is distinguished by the trivial nature and brevity of its prodromal symptoms; the slightness or absence of catarrh and cough; the insignificant fever; the absence of Koplik's spots and of stomatitis; and the presence of tender enlargement of the posterior cervical, mastoid and occipital glands. The rash of rubella is smaller, pinker and more discrete; but a scarlatiniform stage may supervene. The patient never feels or appears so ill as in ordinary measles.

Small-pox may be heralded by a prodromal rash of morbilliform character, which may have a similar distribution to that of measles, save perhaps on the face. Catarrh, stomatitis and Koplik's spots, however, are absent, and the onset is more abrupt than that of measles, and more likely to be signalised by such symptoms as backache, acute shivering, vomiting and prostration.

Measles may, on the other hand, be mistaken for the early eruptive stage of small-pox, for in both an illness for a few days may precede the appearance of a papular rash on the face and upper parts of the body. Catarrh, Koplik's spots and distribution of the rash about the ears, forehead and margins of the hairy scalp are in favour of measles. The temperature, too, continues to rise until the maximum efflorescence, whilst that of small-pox falls with the appearance of the rash. As the rash develops, the shottiness of the small-pox papules and the peculiarities of their distribution become apparent.

Typhus fever may be simulated by measles when the rash of the latter is receding and dusky, and lung complications are present; but the rash of typhus rarely invades the face, which is always affected in measles. The Weil-Felix reaction also is valuable.

Septic rashes in scarlet fever are often morbilliform; but their distribution does not conform to that of the measles rash. *Serum rashes, food rashes* and *drug eruptions* may assume a measly character; but these rashes often prove to be polymorphic when the whole body is examined, as it should be, and, besides, other signs of measles are wanting.

The *macular syphilide* is distinguished by the absence of respiratory catarrh and of Koplik's spots. History of exposure to venereal infection, a

chancre and the accompanying throat symptoms afford a clue. The Wassermann test should be employed.

Prognosis.—In different epidemics the death-rate may vary from 1 or 2 to over 50 per cent. Measles is most fatal to infants and young children, 70 per cent. of the mortality occurring in children under 3 years of age. After the fourth year the death-rate is low. Rickets, tuberculosis, congenital syphilis, malnutrition and chronic bowel complaints are unfavourable factors, and the disease is more fatal among the poor. In the cold season of the year the tendency to respiratory complications is more marked. When the infection occurs in conjunction with whooping-cough or chronic lung disease the mortality is high. Diphtheria is apt to assume the laryngeal form, and is an especially fatal complication. Considerable toxæmia with high fever, cyanosis, muscular tremor and diarrhœa point to a severe attack. Laryngitis, capillary bronchitis and broncho-pneumonia are serious. Cerebral symptoms, such as prolonged stupor or convulsions, are of bad augury. Remarkable recovery has been noticed in some cases of ascending myelitis.

Treatment.—PROPHYLACTIC.—Measles is chiefly disseminated by schools. The difficulty in controlling outbreaks of measles arises from the fact that it is extremely infectious, and the infectivity is present in virulent form for 4 or 5 days before the rash appears. Notification and school closure have been tried with poor results. The best method is to make provision for the early recognition of suspicious symptoms in contacts or to exclude those who have not had measles previously, for a period covering the ninth to the sixteenth day after the occurrence of the first case.

As regards the home, when measles occurs those who have had the disease need not be excluded from school—save from infant classes, but those presumably susceptible should either be excluded for over 16 days from exposure to infection, or, if allowed to attend, be subjected to daily examination.

In ward outbreaks children who have not had measles should be passively immunised, and if possible isolated or, at all events, segregated in small groups.

Serum prophylaxis.—Intramuscular injection of the blood serum of healthy convalescents from measles into susceptible contacts produces a *passive* immunity, which lasts about a month. Injection during the first 5 or 6 days of the incubation period prevents measles if the dose is adequate. Injection after the sixth and before the ninth day will modify the severity of attack, and allow the development of an *active* immunity which is lasting.

The dose is 2 c.c. for each year of a child's age up to a maximum of 10 c.c.; more is needed for adults or if the serum is injected late. In children under 3 years of age it is better to prevent the attack altogether. The most potent serum is obtained from the sixth to the ninth day after defervescence. The donor must be free from syphilis, malaria and tuberculosis, and must not be incubating any other infectious disease. The serum of adults, presumed to have had measles, but not recently, is of some value, but the dose should be doubled. A placental globulin extract has been prepared for use in the same way.

If measles follows the subcutaneous injection of immune serum the rash fails to erupt at the site of injection; this is the *Debré phenomenon*. Immune

serum does not blanch the developed rash. A disquieting feature is the occasional occurrence of infective hepatitis after the administration of convalescent measles serum, sometimes after so long an interval as 3 months.

Systematic taking of temperatures and examination for Koplik's spots and catarrh facilitate early detection of the disease, when patients are under close observation. The wilful exposure of children to the contagion of measles is unjustifiable, as the nature of the resulting attack can never be predicted.

Sixteen days' quarantine from the date of last exposure to infection is usually deemed sufficient, but, owing to the trivial nature of the prodromal symptoms it is better, in the case of schools, to allow a period of 3 weeks to elapse, especially if serum prophylaxis has been attempted. Convalescent patients in the absence of complications are quite free from infectivity at the end of a fortnight from the appearance of the rash.

CURATIVE.—The patient must be confined to bed during the febrile, and also during the prodromal stage, if this be recognised in time. The sick-room should be kept at a temperature of 60° to 65° F., and ventilation effected by means of open windows ; an open fire is also an advantage. The photophobia calls for the avoidance of direct light. Clothing should be light and consist of a flannel or woollen nightdress ; this is sufficient to prevent chill, allows the respiratory muscles full play, and encourages the evaporation of perspiration. Strict attention should be paid to cleansing the mouth and teeth, and the regulation of the bowels. During the febrile stage the diet should be restricted to milk, diluted if necessary with barley water. Tea may be allowed, and fruit juices or barley water given to assuage the thirst.

Twice a day during the febrile period the patient should be washed with tepid water ; but should the attack assume a toxæmic form, accompanied by high fever and delirium, cold sponging or the use of the cold pack is advisable. Amidopyrin, given early, is said to abort the disease, but has its dangers. The hot mustard bath is useful for children when pyrexia is accompanied by indications of circulatory failure.

Laryngitis in the early stage is relieved by steam and the use of a simple expectorant mixture, to which a sedative may be added. The croupy symptoms usually subside without necessitating tracheotomy or intubation. The possibility of the presence of diphtheria renders a bacteriological examination essential.

Laryngitis which persists after the eruption may be alleviated by the inhalation of compound tincture of benzoin or lysol in the strength of 60 minims to the pint of boiling water. The cough is relieved by a simple linctus, or one containing $\frac{1}{8}$ grain of morphine or other sedative. Late laryngitis if diphtheritic needs antitoxin. Bronchitis and broncho-pneumonia call for prompt treatment. A jacket of Gamgee tissue should be applied. If the cough is dry and irritating, steam often relieves. An expectorant mixture containing ipecacuanha and a small quantity of potassium iodide is useful. Sulphonamides may prove valuable. Sometimes a single mustard and linseed poultice gives great relief. As the cough becomes looser, steam should be discarded and free ventilation arranged. It is well to separate cases with broncho-pneumonia from others, as the condition is believed to be infectious. Treatment of the broncho-pneumonia of measles in the open air, where circum-

stances and weather permit, gives excellent results. Oxygen is valuable where there is much respiratory distress and cyanosis. Cardiac dilatation is an indication for the application of leeches. Frequent small meals are preferable to overloading the stomach.

Conjunctivitis should be met by bathing the eyes with boric lotion and the application of boric ointment to the lids. In severe cases, drops of silver nitrate solution, 2 grains to the ounce, should be instilled night and morning, or a 2–10 per cent. solution of silver protein used. Should the cornea ulcerate, atropine drops should be employed and oculent hydrarg. oxid. applied. Eye bandages are undesirable.

Stomatitis usually subsides quickly; the mouth should be cleansed with a lotion containing chlorate of potash (10 grains to 1 fl. ounce). In the presence of ulceration due to Vincent's organism, neoarsphenamine should be injected or applied locally. The supervention of noma calls for bacteriological examination and antitoxin or surgical interference in the way of cauterisation or free excision. Entero-colitis is managed on the same lines as infantile epidemic diarrhœa.

Convulsions and encephalo-myelitis are treated by sedatives and lumbar puncture, repeated if the cerebro-spinal fluid is under increased pressure. Intramuscular, intravenous or intrathecal injection of 10 c.c. of blood serum from a recently recovered case with this complication, if obtainable, seems worthy of a trial.

In an uncomplicated case of measles the patient may be allowed up 2 or 3 days after the temperature subsides. Supervision should be exercised during the convalescence of severe cases, and the possibility of later tuberculosis borne in mind. Ear discharges call for skilled treatment, as they may become chronic.

RUBELLA

Synonyms.—German Measles, Rötheln.

Rubella is quite distinct from ordinary measles and from scarlet fever. It protects only against itself. Amongst the exanthemata it is characterised by its long incubation period, its short invasive stage, its benign course and its seasonal prevalence.

Ætiology.—The infectivity is less than that of measles and of short duration. Like measles it is infectious for a day or two before the eruption appears. Infection is facilitated by close contact and there is no evidence that the disease is spread by fomites. Infection through an intermediary cannot be considered proved. The infective agent is unknown, but a filtrable virus has been suspected.

Rubella is prevalent in the first half of the year. Cases increase from January to a maximum in May and June. After that an abrupt fall ensues. A series of local outbreaks usually occurs, determined by the aggregation of a number of unprotected young adults. A more or less pronounced epidemic wave occurs every third or fourth year. The maximum incidence is at a later age period than that of measles, but even the youngest infants have been known to take the disease. Its frequency much diminishes after the age of 30. Sex is without influence.

Symptoms.—The incubation period, although variously stated to be from 7 to 22 days, is usually 17 or 18 days.

Premonitory symptoms are mild or altogether absent, but a short catarrhal stage usually occurs, the rash making its appearance within 24 hours. Rarely a longer prodromal period of ill-defined illness occurs before the eruption. The characteristic adenitis of the mastoid, occipital, cervical or other lymph glands can, more often than not, be detected for a day or two, exceptionally even a week or longer, before the appearance of the rash.

The rash is often dimorphic. Macular, slightly papular and morbilliform in its progress, it frequently fuses and becomes scarlatiniform in its second stage. Discrete spots first appear on the face or neck; they invade the circumoral region and may be found behind the ears and on the scalp. Sometimes they are first found on the wrists, chest, shoulders, or even on the legs. They are smaller than the papules of measles, pale pink in colour, and tend to cluster in small groups. The rash quickly extends to the trunk and limbs and in most cases as quickly fades. On the second day the face is no longer spotty but appears diffusely erythematous ("sunburnt"). Sometimes the outbreak of the eruption is halting in its progress. The scarlatiniform stage is not developed in all attacks; it is due to the fusion of the discrete elements, and is generally best marked on the trunk, especially so on the back. It becomes most apparent on the second day of the eruption. The rash rarely lasts more than 72 hours and hardly stains the skin, thus contrasting with measles.

The mucous membrane of the mouth is not inflamed, and Koplik's spots never occur. The tonsils may be slightly swollen and reddened, sometimes a follicular exudate is present. Some degree of pharyngeal catarrh is evident, and the tongue may be lightly coated. A fine vesiculation and congestion of the soft palate are often seen, and the orifices of Stenson's ducts may be vividly injected. The gums may be injected and tender. The conjunctivæ are pink and the eyes slightly suffused. Photophobia is rare. Fever is slight, even when the rash is intense. Often there is no fever at all. The pulse and respiration rates are only increased in proportion to the febrile disturbance.

A tender adenitis is very distinctive. The mastoid and occipital glands may rapidly attain the size of peas; the posterior cervical glands are also enlarged, frequently too those in the axillæ and groins. The enlarged glands are firm, tender and discrete; suppuration never occurs. As a rule resolution takes place rapidly when the rash subsides. The urine presents no special characteristics.

As in the case of morbilli, a leucocytosis occurs during the incubation period, but a leucopenia with a relative increase of lymphocytes is found in the eruptive stage. More distinctive is a high percentage of plasma cells and Türck cells.

Convalescence is remarkably speedy. Slight furfuraceous desquamation may occur.

Complications.—Complications and sequelæ are for all practical purposes non-existent. When they do occur they are trivial and take the form of mild recurrent sore throat, slight laryngitis, slight bronchial catarrh, rheumatism, rarely acute, or transient albuminuria. Otitis is very rare, and meningeal symptoms, encephalo-myelitis, or polyneuritis, rarer still.

On occasions, epidemics of rubella of more severe type, approximating in symptoms and sequelæ much more closely to measles, have been described.

Diagnosis.—The disease has a similarity to measles and scarlet fever, especially when the latter occurs in a mild form. In addition, the rash of rubella must be distinguished from toxic and drug rashes, from the eruption of secondary syphilis, from glandular fever, and from certain skin diseases.

Measles is differentiated by the following points. The incubation period is shorter, being 14 days from exposure to the appearance of the rash; cough and catarrhal symptoms are marked, the mucous membrane of the mouth is inflamed and Koplik's spots are present. The rash appears later, is darker, more persistent, and stains. There is no late scarlatiniform stage. Fever is more pronounced, and the mastoid and occipital glands are not especially enlarged. Pulmonary complications are much more likely to occur.

Rubella is often mistaken for scarlet fever. Distinctive points in favour of the latter are: the short incubation period; the occurrence of such initial symptoms as vomiting, marked faucial inflammation, shivering or severe headache. The fever is high at onset and the pulse disproportionately rapid. The circumoral region is free from rash, and by the fourth day the tongue has peeled. The occurrence of such sequelæ as arthritis, cervical adenitis and nephritis, also typical pinhole or lamellar desquamation, will clinch the diagnosis. Even in the scarlatiniform stage of rubella, discrete measly elements may generally be detected about the edges of the rash on the forearms, wrists, legs and ankles. An eruptive fever which simulates measles at its onset and scarlet fever later, is generally rubella. Occasionally glandular fever (*q.v.*) resembles rubella.

Toxic, enema and drug rashes may bear a resemblance to the rash of rubella, but as a rule these rashes are very irregular in their distribution and polymorphic in character. The characteristic glandular enlargement and slight catarrh of rubella are absent.

Of skin diseases, erythema scarlatiniforme and pityriasis rosea are sometimes mistaken for rubella. The first named bears a greater resemblance to scarlet fever; unlike rubella, it avoids the face, does not give rise to swelling of the mastoid and occipital glands, and shows a great tendency to recur.

Pityriasis rosea, itself possibly an infective fever, is distinguished by a herald patch which precedes the general eruption, and the fact that the latter usually appears first on the upper part of the trunk. The rash often shows commingled macular and ringed lesions. The patches are slightly scaly and are decidedly larger and more persistent than the papules of rubella. There is no catarrh and no conspicuous glandular enlargement about the head. The patches desquamate in a characteristic manner from their centres, which are fawn coloured, towards the margins, which are slightly elevated and darker.

Secondary syphilides bear a superficial resemblance to the rash of rubella, but are distinguished by the presence of a primary sore, the characteristic throat and the conspicuous increase in size, and shottiness of the glands in the vicinity of the chancre. The Wassermann reaction is of value.

The Paul-Bunnell reaction will distinguish glandular fever.

Prognosis.—Recovery is the rule; second attacks are known, but not common, and relapse is very rare.

Treatment.—Prophylactic.—As the incubation period is long a quaran-

tine of 3 weeks is theoretically necessary for contacts, but is rarely imposed. They may be watched or isolated from the tenth to the twenty-first day from exposure to infection. Early warning of the imminence of attack may be gained by carefully watching the mastoid and occipital glands.

CURATIVE.—The patient should be isolated and kept in bed until all symptoms have subsided. In 7 days all infectivity has ceased, provided there is no persistence of faucial, nasal, respiratory or other symptoms.

SMALL-POX

Synonym.—Variola.

Definition.—An acute, specific, highly infectious fever, characterised by a definite incubation period and a distinctively distributed, deep-seated eruption which passes through the stages of papule, vesicle, pustule and crust. The fever shows two phases—a remission at the outbreak of the rash being followed by a reaccession on the onset of the pustular stage.

Ætiology.—All races, both sexes, and persons of every age are susceptible if unprotected by a previous attack, or by efficient vaccination. This general liability is most evident when the disease is introduced for the first time into a new community; under such conditions it may decimate the population. Its present-day incidence on adults is accounted for by vaccination in infancy; in endemic centres it was, prior to the introduction of vaccination, a disease of early childhood. Small-pox has at times been epidemic in every civilised country, following trade routes and the channels of communication. It is more severe in hot climates. Coloured races are said to take it badly. Unlike scarlet fever and measles, it frequently attacks infants at the breast. When small-pox occurs during pregnancy, infection of the fœtus is common but not inevitable. Abortion or premature delivery is to be expected in all severe attacks. The fœtus contracts the disease in utero, usually during the pre-eruptive (septicæmic) stage in the mother, the incubation period being shorter than the usual 14 days for contact infection via the respiratory tract, in some instances fœtal infection is acquired at the time of separation of the placenta. Few of the children born in these circumstances survive, sometimes they actually show the rash or its scars at birth.

In England and temperate climes most outbreaks occur during the winter and spring, and tend to die out with the commencement of summer. Small-pox protects against itself, and second attacks are rare. Vaccination gives complete immunity for some years and partial immunity usually persists afterwards. Complete natural immunity is very rare, but is reported. Inoculated small-pox affords more complete immunity than vaccination.

Infection with small-pox is, almost certainly, through the respiratory tract, and may be direct or indirect, *i.e.* by contact, which need not be very close, with a patient suffering from the disease or through the medium of objects infected by the sick person. Intermediaries may carry the contagium in their clothing or in their hair. The greater incidence in the neighbourhood of small-pox hospitals suggests the possibility of aerial convection of the virus for considerable distances, perhaps exceeding a mile, but the influence of human carriers in these cases is hard to eliminate. Bedding, clothing and rags may retain their infectivity for considerable periods of

time, especially when stored. Transmission by flies and domestic animals is regarded as a possibility. The infectivity of small-pox is slight at the time of the symptoms of onset, and is much greater when the eruption appears. It continues until all the scabs have separated. The virus is very resistant and long persists in the dry scales and crusts shed from the body. Corpses of those recently dead from small-pox can transmit the disease. Tramps are often responsible for the conveyance of infection from one locality to another.

There can be no doubt that small-pox is due to a living virus. Minute, but characteristic, intracellular bodies are found in the epithelial cells of the pocks of small-pox and vaccinia, and also in the cornea of the rabbit, after scarification with the virus of these diseases. They are known as *Guarnieri bodies* and some apparently contain the "elementary bodies" of Paschen. The elementary bodies of small-pox and of variola minor are agglutinated by the sera of patients convalescent from either form of the disease.

Pathology.—The cutaneous lesion of small-pox lies in the deeper layers of the epidermis. Vesiculation is due to serous exudation between the cells. Loculation is caused by vertical strands of degenerated epithelial cells which radiate from the base of the pock. The tenseness of the vesicle and tethering of the covering by this reticulum cause the pock to be umbilicated. In malignant attacks, where the pocks are flaccid, and in the old and debilitated where a similar condition may obtain, umbilication is often absent. With pustulation the fibres of the reticulum are ruptured and the pock becomes dome-shaped. The suppuration is attributed to secondary infection with extraneous organisms, particularly with streptococci. On mucous membranes the vesicles rupture almost as soon as formed and are rapidly converted into shallow ulcers. The chief blood change is an initial leucopenia, followed after the first week by a leucocytosis in which mononuclear cells preponderate. A secondary anæmia may become pronounced. The post-mortem appearances are those usually found in acute infective processes. The rash persists, the liver is often much enlarged, the spleen swollen, and the lungs broncho-pneumonic. Particular attention has been drawn to the presence of local necroses in the liver, testicles and bone marrow. These are often infiltrated with mononuclear basophil cells. In hæmorrhagic small-pox, petechial and purpuric hæmorrhages are found in the skin, mucous membranes, lungs and other viscera, sometimes also in the retro-peritoneal tissues and the roots of the mesenteries.

Symptoms.—*Unmodified small-pox; Variola major.*

Period of incubation.—Taking the first symptoms of invasion, this is from 10 to 14 days. The average period is 12, or counting to the appearance of the rash, 14 days. Extremes of 5 to 23 days are mentioned but are rare. In inoculated small-pox the generalised eruption appears on the eighth to the eleventh day.

Period of invasion.—In a typical attack the invasive symptoms are sudden and of great intensity. The most prominent are severe chills or rigors, marked pyrexia, severe frontal headache and intense pain across the loins. The temperature quickly reaches a maximum of 103° to 104° F., and is accompanied by severe prostration. Giddiness and nausea are present and vomiting may occur, particularly in children. Delirium, mental symptoms and even suicidal tendencies may accompany the invasive stage. With these

severe symptoms are coupled more ordinary febrile manifestations, such as anorexia, thirst, coated tongue and disturbed sleep. The breath is offensive, the skin usually hot and dry but sometimes perspiring, and the bowels constipated. There are, however, mild attacks in which the symptoms of invasion are much less severe, and even in more severe attacks pain across the loins is not always present. Mild invasive symptoms usually presage a mild eruption; with a severe invasion the attack is generally, although not invariably, grave.

Prodromal rashes.—These may precede the proper eruption for 1 or 2 days. They are not always present. There are two types, one purely erythematous, the other petechial or hæmorrhagic with or without accompanying erythema. The pure erythemas are of a bright red or dusky purplish colour and may appear on the trunk, where they are often patchy, or be limited to the bony prominences and extensor surfaces of the limbs. They may suggest the rash of scarlet fever or bear a superficial resemblance to that of measles. The hæmorrhagic or petechial rash, which often has at first a dusky erythematous background, is more characteristic. It appears in the flexures of the groins, which are stippled with small petechiæ; it invades the thigh for an inch or two and extends in an ill-defined manner on to the abdomen. Sometimes it extends towards the axilla and may be found on the back of the neck and flexures of the knees. The petechial rashes are persistent and indicate a severe attack. The erythemas are fugitive and of good prognostic import; the only exception is a very brilliant universal erythema of face, trunk and limbs which sometimes ushers in hæmorrhagic small-pox.

The eruption.—On the third day the symptoms of invasion are at their maximum and the eruption appears, showing first on the forehead and temples near the edge of the hairy scalp and also on the wrists. It extends rapidly over the body, but always affects most the parts usually uncovered and those most exposed to pressure, friction or other irritation. It is least profuse on the abdomen and in the groins, somewhat more marked on the chest, still more marked on the back, especially across the shoulders, thicker still on the arms, choosing their distal portions, and most profuse of all on the face, especially its upper part. It reaches the lower extremities within 24 hours of its first appearance. Meantime the lesions multiply on the parts already affected, the eruption becoming thick on the face, and perhaps in the scalp, whilst still scanty on the parts invaded later. In 3 days it will have attained its full density, but the earlier lesions will be in a slightly more advanced stage of development than those which appeared later.

In a characteristic way it avoids depressions, flexures and protected flexor surfaces, such as the armpits, flanks, groins, orbital hollows and supraclavicular fossæ. The escape of the axillæ and scantiness of rash on the flanks are marked. Abnormal irritation by clothing, irritants or scratching may determine a profuse eruption in areas on which, ordinarily, pocks are scanty. The pocks are aggregated over prominent bones and outstanding tendons, but the clavicles and malleoli are exceptions to this rule. The rash is more or less symmetrical; one arm will not escape when the other is involved.

On the *first* day of efflorescence the rash consists of small dull-red *macules*. Within 24 hours these are becoming obvious *papules* which feel shotty when pinched up between the finger and thumb, the hardness being best

marked on the face, hands and forearms. On the *third* day of eruption many of the papules have become converted into *vesicles*, but the commencement of vesiculation may be recognised on the summits of the papules at an even earlier stage. By the fourth or fifth day the eruption is completely vesicular and the early toxæmic symptoms and fever may have entirely subsided. The vesicles, which are circular in outline, slowly increase in size and become surrounded by an inflammatory areola. They are now about the size of split peas, greyish in colour, and set in the skin rather than on its surface. Umbilication is evident and loculation is proved by their failure to collapse when transfixed by a sterile needle. The contents of the vesicles remain clear for 24 hours only; they then gradually become purulent, so that by the *fifth* day *pustules* are in evidence on the face and by the eighth day are universal. With pustulation, the pocks soften, become flat-topped and lose their areolæ. Reaccession of fever with constitutional symptoms and often delirium, the *secondary suppurative fever*, accompanies the process of suppuration or maturation. Where the pustules are plentiful a marked inflammatory œdema of the skin may now appear, causing the features to become much swollen and impeding the movements of the hands and fingers. Much tenderness accompanies this œdema, and the patient may also be tormented by itching. Suppuration destroys the loculation of the vesicles and also obliterates umbilication. Adjacent lesions, particularly on the face and hands, may run together in the vesicular and pustular stage—a process which produces the *confluent rash*, and is a sign of severe infection. On the *ninth* and *tenth* day of eruption the pustules begin to *desiccate* and *scab*, some first rupture or are torn by scratching, and collapse. Brown or black crusts result which separate by the end of the thirteenth or fourteenth day, but where the skin is very thick, as on the palms and soles, the dried-up unruptured pustules may form deep-seated "seeds" which may take weeks to work their way to the surface.

To summarise: the rash is papular on the first to the third day; vesicular from the third to the fifth; pustular from the fifth to the ninth, and desiccating from the ninth to the seventeenth.

The cutaneous eruption is accompanied by an outcrop on the mucous membranes of the mouth, nose and pharynx. In severe cases the larynx, bronchi, gullet and even the stomach may also be affected. On the mucous membranes vesicles are soon transformed into shallow grey ulcers. Vesiculation may be observed on the palate, whilst the lesions are still indeterminate on the skin. In consequence of the eruption the fauces and tongue become sore, the nose is obstructed and deglutition is painful. Implication of the larynx will cause hoarseness or aphonia and even dangerous œdema. The mucous membranes of the vulva, vagina and rectum may also be involved.

The fever (Fig. 4) of invasion reaches its acme with the appearance of the rash, then it falls, but not immediately. It is generally normal by the fifth day of the eruption, often before this. It is at this stage, in the milder attacks with scanty rash, the patient may attempt to resume his ordinary occupation, and, in modified cases, very little further febrile disturbance may ensue. Ordinarily, however, the secondary suppurative fever now sets in and reaches its acme about the ninth or tenth day of the eruption. Its duration in the more severe cases is from 10 days to a fortnight. In severe and confluent

cases, the remission of temperature in the vesicular stage may be ill-marked or absent. The pulse and respirations are quickened proportionally to the degree of fever present, but in grave cases the respirations become shallow and irregular, and the pulse accelerated and feeble.

The urine is febrile in character. Some albumin may be present, and a diazo-reaction may be obtained.

Owing to the depth of the lesions in the skin, depressed scars are left, the amount of pitting depending on the degree of suppuration. The pits show a reddish staining which may persist for months. Some desquamation may accompany the separation of the crusts, particularly on the feet and hands. The hair often falls out freely. Convalescence is, in favourable cases, rapid and complete.

Small-pox may assume severe, modified or benign forms :

Severe types of small-pox.—These comprise the confluent and hæmorrhagic

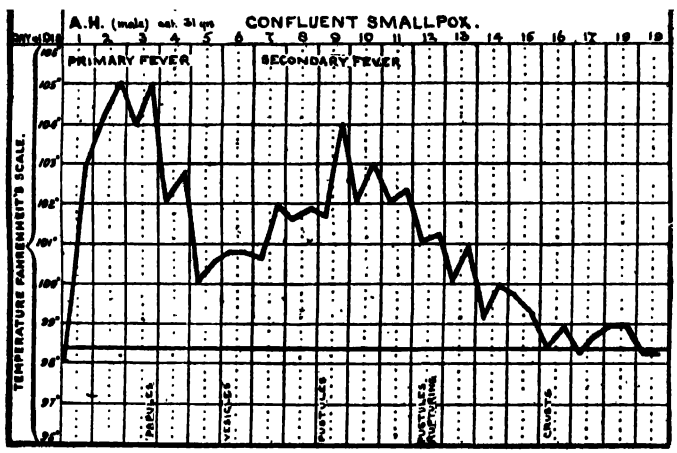

FIG. 4.—Confluent small-pox in an unvaccinated adult.

varieties. *Confluent small-pox* is characterised by fusion of the lesions, particularly on the face and hands. The rash may fuse whilst still papular, but more commonly does so in the vesicular and pustular stages. In such cases the toxæmia is severe and the remission of symptoms before the stage of pustulation may be absent or ill-marked. Delirium is common, and the secondary fever high. Inflammatory œdema is very marked, the features may become quite unrecognisable and the confluent pocks may form a continuous sheet of pus. Severe conjunctivitis, nasal obstruction, salivation, cough, aphonia and diarrhœa are common. Some patients pass into a typhoid condition. An offensive odour emanates from the skin, circulatory failure is progressive, and death may occur towards the end of the second week.

Hæmorrhagic small-pox.—In the most malignant variety, purpuric flecks and patches may appear in the skin before the development of the eruption, and are accompanied by subconjunctival hæmorrhages and bleeding from the mucous membranes. Initial symptoms, in particular backache, are

severe, and prodromal rashes common. The respiration is hurried and the breath fœtid, but the temperature not necessarily very high. Death may occur before the outbreak of the proper eruption gives a clue to the nature of the infection, but often towards the end careful inspection may show a few papular elements struggling to appear.

In other cases the bleeding first manifests itself about the time of the eruption, occurring in the form of petechiæ or of circular spots between the lesions and also infiltrating the bases of the vesicles and staining their contents. The vesicles are often badly developed, confluent and of a violaceous hue. Bruises form easily in the skin, and hæmaturia, epistaxis, hæmatemesis or uterine hæmorrhage may appear. The breath has a sickly odour.

The mere presence of blood-stained contents in the vesicles, especially those on the legs, without hæmorrhages into the bases of the pocks, in the skin and elsewhere, is not of bad prognostic importance.

Modified small-pox or varioloid.—Small-pox of a very mild type may occur in vaccinated subjects. In such cases initial symptoms may be slight, and the eruption, although typical, is scanty; sometimes it fails to appear. More commonly, the initial symptoms are severe, and the rash appears early, but it is generally sparse and discrete, tends to evolve quickly, and many of its elements fail to progress beyond the papular or vesicular stage, the suppurative fever being slight or absent. The lesions, which are often small, are superficial and may be unilocular, sometimes they appear fleshy and wart-like. The modification is most evident on the face. In such cases the arrest of development leading to the juxtaposition of papules, vesicles and small pustules may cause a resemblance to chicken-pox, but the distribution remains characteristic.

Variola minor.—From time to time a benign type of small-pox has prevailed in many parts of the world. The names alastrim, amaas, varioloid varicella and para-variola also designate this disease. It differs from ordinary small-pox in its mild course, low mortality (0·5 to 2 per cent.), lesser infectivity, the usual absence of secondary fever, the occurrence of residual pigmentation rather than pitting, and incidence on adults rather than on children.

The incubation period is 10 to 15 days, or longer. Invasion is abrupt, and may be accompanied by muscular pains, backache, vomiting and sometimes high fever, but many cases are ambulatory. The rash never appears before the third day, more commonly on the fourth or fifth. It is seen first on the face, then on the forearms and trunk, and within 12 hours on the lower limbs. The eruption may be scanty or moderately profuse. It rarely comes out in crops, but in any case the initial lesions are more advanced than those which follow. Maturation is more rapid than in variola major, papular and vesicular stages each lasting 2 days, pustulation beginning on the fifth day, and scabbing on the face being evident within a week. There is, as a rule, no secondary fever.

The distribution of the eruption is classical, the rash favouring the face and extremities rather than the trunk. On the limbs, the distal parts, and on the trunk the upper part of the back, rather than the abdomen and chest, are involved. Much weight is attributed to the detection of a few deep-seated lesions in the skin of the thenar and hypothenar eminences.

The lesions are more superficial than in variola major, but not so superficial as the blebs of chicken-pox. They are not always spherical, and are

often unilocular and not umbilicated. Mature vesicles have an opalescent appearance, and the crusts are of a deep amber colour. It is easy to understand why the disease is so often mistaken for chicken-pox. The distribution of the rash is the important diagnostic criterion. Although vaccination protects against v. minor the converse is not invariably true. As a rule, vaccination in the eruptive stage fails, but may take in modified form later.

Although serological tests fail to differentiate variola minor from variola major, histological examination shows that the inclusion bodies of v. minor show differences in numbers, size, staining reactions and localisation in the vesicles when compared with v. major.

Complications.—During the later stages of small-pox and in convalescence, boils and superficial abscesses often cause trouble. Septic rashes, erysipelatous or impetiginous infections may spread from the pocks. The cervical and axillary glands may become enlarged or even suppurate. In the more severe cases, bed-sores may rapidly form over pressure points. Rarely death is due to septicæmia arising from these cutaneous infections.

Ocular complications are important. Conjunctivitis is common. Pustules may form on the palpebral or ocular conjunctiva. The eyelids often become inflamed and œdematous. A rapidly spreading keratitis may lead to sloughing of the cornea, but corneal ulcers are more common and sometimes lead to perforation and panophthalmitis. Iritis is rare. Retinal hæmorrhages sometimes cause blindness. The scars of the corneal ulcers may much impair the sight. Otitis media is comparatively common.

Laryngeal inflammation may be so severe as to necessitate tracheotomy, and may lead to perichondritis and necrosis. Bronchitis and bronchopneumonia are frequent and often accelerate death. Lobar pneumonia and purulent pleurisy are rare. Endocarditis and pericarditis are exceptional, but degenerative changes in the myocardium are not infrequent. Occasionally a destructive arthritis supervenes; it is said to be more common in childhood. Although albuminuria is often found, a true nephritis is uncommon.

Parotitis is looked upon as a secondary duct infection from the mouth. Orchitis sometimes occurs during the acute stage.

As in other fevers encephalo-myelitis and neuritis may occur. On recovery from the toxæmic stage speech may be completely lost, but it returns. Less favourable are bulbar or limb paralysis, with or without derangement of sphincter control.

Disfigurement of the face, permanent blindness, deafness and sometimes alopecia may be the legacies of a severe attack.

Diagnosis.—The whole body should be stripped and examined in a good light. In some cases a preliminary bath is needful. Attention should first be focused on the distribution rather than on the characters of the rash. The individual lesions should be dotted on an outline diagram of the body, and a numerical comparison made of those on the abdomen, chest, back, upper arms, forearms, face, thighs and legs. Too great reliance should not be placed on shottiness or umbilication. The condition as to vaccination should be ascertained and the nature of any prevailing epidemic borne in mind.

The initial fever may itself lead to difficulty in diagnosis; the symptoms of onset are somewhat similar to those met with in other acute diseases, particularly influenza, acute rheumatism, pneumonia and cerebro-spinal fever.

Severe prostration and backache, when present, are suggestive. Often the diagnosis is not certain until the true eruption appears on the third day and the fever subsides, but the appearance of a petechial prodromal rash in the groins may enable earlier recognition. As regards influenza, it is more common for small-pox to be at first mistaken for this disease than for the converse to occur. Lumbar puncture is available in cerebro-spinal fever. In pneumonia sooner or later lung signs appear. Precipitate certification of a supposed case of small-pox, even in a contact, is unwise; it is better to await the appearance of the rash, remembering this should appear first on the forehead, near the roots of the hair, the cheek bones, sides of the nose, wrists, hands and forearms. The interior of the mouth should also be inspected and any parts of the skin which have been subjected to special irritation.

The prodromal rashes, if purpuric, may be confused with different varieties of purpura; if erythematous, with scarlet fever, measles, rubella, urticaria or other forms of erythema.

The characteristic groin incidence of the purpuric rash of small-pox should be remembered, and is of great assistance in diagnosis. More widespread purpuric rashes, however, are at times misdiagnosed as febrile purpura until the occurrence of small-pox in contacts reveals their true nature. Conversely, febrile purpura and purpuric rashes occurring in ulcerative endocarditis, cerebro-spinal fever and other conditions may be mistakenly thought to indicate small-pox. The distribution of the rash and the character of accompanying symptoms should be noted. Physical examination of the organs may reveal signs which help to clear up the diagnosis, which may be very difficult.

A scarlatiniform prodromal rash is distinguished from scarlet fever by the absence of tonsillitis and of punctate redness of the soft palate. The rash on the skin is not definitely punctate and the area of circumoral pallor is wanting. The tongue is not typical nor are the tonsillar lymph glands enlarged. The Schultz-Charlton test is negative.

Morbilliform prodromal rashes bear only a very superficial resemblance to measles. The diagnosis is discussed later. Nor should rubella be confused if its characters be borne in mind. The initial erythemas may resemble those induced by antitoxic serum, by soap enemas and by drugs. The characters of these rashes are given in the article on scarlet fever.

The *true eruption of small-pox* may be confused with measles, chicken-pox, perhaps typhoid or typhus, also with various forms of papular erythema, urticaria, acne, papular and pustular syphilides, and glanders. Sometimes drug rashes, particularly those due to iodides, lead to mistakes. Measles on the face may bear a close resemblance to the papular eruption of small-pox. It is distinguished by the catarrhal symptoms, Koplik's spots, the distribution of the rash on the body, and the fact the temperature tends to rise as the eruption increases instead of falling as it does in small-pox.

The differentiation of some cases of chicken-pox is a difficulty. Chicken-pox is a disease of childhood whilst small-pox chiefly affects adults (although with neglect of vaccination its incidence in childhood may again increase), but cases of chicken-pox in the adult are not infrequent, and in them prodromal symptoms may be sharp and the rash not appear until the second or third day. Chicken-pox presents the following distinctive characters:

1. The rash of chicken-pox appears first on the trunk, and is thickest on

the trunk, face, upper arms and thighs. It avoids the extremities of the limbs. It does not so markedly select irritated areas, nor does it avoid the axilla and groin. The presence of many lesions on the palms and soles is greatly against chicken-pox.

2. The eruption comes out in distinct crops over 3 to 5 days or more.

3. The vesicles develop much more rapidly and are mature in 24 hours. Vesicles are not seen at this period in small-pox.

4. The lesions are superficial and unilocular, rarely umbilicated. Their bases are not indurated. Near flexures they may assume an oval outline, sometimes they are irregular or crenated.

5. Pocks of all stages of development may be present at the same time on a given area of skin.

6. The lesions are smaller. Pustules and scabs half an inch across are almost certainly due to small-pox.

7. Successful vaccination within 5 years or revaccination within 10 years is evidence against the disease being small-pox. Chicken-pox does not protect against successful vaccination in an unprotected individual. If the disease is small-pox, vaccination will prove unsuccessful. This rule, however, is not absolute. Vaccination may prove successful in anomalous forms of small-pox, and has been alleged to take in ordinary small-pox on rare occasions.

Confusion with typhoid and typhus is uncommon, and should be eliminated by taking into consideration the distribution of the rash and character of the other symptoms. In distinguishing other skin eruptions it should be remembered erythemas are often polymorphic. They may show occasional vesiculation which is quite superficial and are sometimes febrile. Acne affects the face, shoulders, back and chest; it is chronic, afebrile, and often associated with comedones and scars. The lesions may be pustular but are never vesicular. The lesions are not found on the forearms or hands.

If syphilis is borne in mind its eruptions are not likely to be mistaken. Reliance must be placed upon their distribution, polymorphic character, other signs of syphilis, the history and the Wassermann reaction. A patient with syphilis may also have small-pox. Glanders is rare, but when the nodules on the face suppurate and are accompanied by fever, small-pox may be suggested. There is usually a nasal discharge and a history of association with horses. Bacteriological examination will show the *Bacillus mallei*.

Certain laboratory tests have been elaborated for the detection of small-pox. Of these, Paul's test is of value. It is carried out as follows. A rabbit's eyes are cocainised. One is scarified with the contents of a suspected pock, the other is simply scarified as a control. At the end of 48 hours the rabbit is killed and the eyes are examined in a sublimate alcohol bath. In the case of small-pox or vaccinia, but not of chicken-pox or other vesicular eruption, the inoculated cornea shows opaque white elevations on a milky background. The other cornea is evenly opaque without epithelial plaques. Guarnieri bodies are present in the plaques.

A more certain test and one more easy to apply and appraise is intradermal inoculation of the rabbit with material from a small-pox vesicle. After a short incubation period a characteristic inflammatory reaction ensues. This reaction remains in abeyance when serum from a rabbit hyperimmunised with vaccinia virus is mixed with the small-pox material before injection

into the dermis (Ledingham, Defries and M'Kinnon). There is also a "flocculation test" based on the fact that an extract of small-pox crusts is flocculated when mixed with the serum of a vaccinated rabbit.

Prognosis.—Natural small-pox has a mortality which varies from 25 to even 40 per cent. The prognosis may be considered under the following heads: (1) The vaccinal condition of the patient; (2) the age; (3) the nature of the attack; and (4) the character of the prevailing epidemic.

1. When a vaccinated person takes small-pox the nature of the attack usually indicates some residual immunity, the severity of the disease being less and the mortality much lower than in the unvaccinated. The presence of large, well-foveated vaccination scars renders the prognosis very favourable. After the age of 15 the protective influence of infantile vaccination will to a large extent have disappeared, but revaccination at puberty, properly performed, confers a high degree of immunity for the rest of life.

2. The death-rate in the first 5 years of life is very high and may exceed 40 per cent. After that there is a fall, at first gradual, then considerable, up to the age of 15 or 20, which is the most favourable period. Subsequently the mortality rises steadily and may even exceed the figures given for the first quinquennium. In the vaccinated, however, the younger the patient the more certain is recovery. If revaccination has not been performed, as age increases the mortality does so also, and may reach 15 per cent. in persons over 30 years of age.

3. The nature of the symptoms is important. Mild invasion presages a mild attack. Severe invasive symptoms usually, but not invariably, mean a severe infection, but they may precede mild attacks in the vaccinated and sometimes in others. Prodromal rashes of a vivid lobster hue, especially if petechiæ be present, are the heralds of grave, often hæmorrhagic infections. Very intense backache is also an ominous invasive symptom. The more profuse the pustular rash the worse the prognosis, but the intensity of the suppurative stage is much modified by previous vaccination. Confluent eruptions mean a bad outlook, whilst patients in whom the rash remains discrete usually recover. Hæmorrhagic small-pox is always fatal.

Other unfavourable symptoms are incomplete remission between the primary and secondary fever, sleeplessness, active delirium, especially in drinkers, considerable implication of the larynx and broncho-pneumonia. The influence of pregnancy in inducing abortion and miscarriage has already been mentioned.

4. Epidemics vary much in their severity and mortality. In some the disease is so slight and the mortality so low, that doubts arise whether the epidemic is really small-pox.

Treatment.—PROPHYLACTIC.—Efficient vaccination and revaccination are the most powerful safeguards. The chief measures to be taken when the disease is recognised are the following: (1) Prompt removal of the patient to an isolation hospital. (2) Thorough disinfection of infected rooms and clothing. (3) Immediate vaccination or revaccination of all other members of the household and of contacts. Four or even more days after exposure vaccination may prove effectual in preventing the disease, at all events will modify it. (4) Quarantining of contacts for 16 days, or a daily inspection so that initial symptoms may be detected at once. (5) Notification of schools or institutions attended by inmates of the same house.

Inoculation with small-pox, which prior to vaccination was a method of prophylaxis, is said in some instances to have a mortality of 2 or 3 per cent.; but even this compares favourably with a mortality of 50 per cent. as seen in some epidemics of ordinary small-pox. Inoculation, however, was found to spread the disease, and so has, in England, been made a penal offence.

CURATIVE.—This is purely symptomatic. Abundance of fresh air, cool surroundings, and not too great a weight of bedclothes, fluid diet, regulation of the bowels, and tepid sponging night and morning form the regular routine. The mouth should be cleansed regularly with peroxide of hydrogen, alkaline carbolic lotion, or some other mild antiseptic, and the nose gently douched or liquid paraffin instilled. A water pillow may be necessary in some cases. Severe pain in the head and back during the invasive stage may be mitigated by the application of an ice-bag to the scalp and use of fomentations to the back; at the same time aspirin, phenacetin, or chloral and bromide may give relief; but the drug most generally useful, both in this stage and in the sleeplessness, delirium and discomfort of the secondary fever, is opium in the form of 10 grains of Dover's powder. Sometimes paraldehyde is effectual. Delirious patients should never be left alone. The intractable vomiting of the early stage is allayed by citrating or peptonising the milk or substituting ice and champagne. Liquor iodi mitis in 5-minim doses is also useful. When fever continues high and is accompanied by toxæmia and delirium, tepid sponging may be replaced by hot or cold packs with advantage. Many methods have been tried of aborting the eruption and preventing the subsequent pitting. None is effectual, but there is hope that sulphonamides may prove of use. Evacuation of the contents of the pocks as soon as fluid appeared in them used to be recommended. Some advocate painting the face with liquor iodi mitis, diluted if painful, twice a day for the first 8 or 10 days, and then applying soft paraffin; or, better, commencing in the papular stage, a saturated (5 per cent.) solution of potassium permanganate may be painted over the whole body three times a day until scabbing begins, and afterwards less frequently. The application of a lint mask soaked in glycerin is useful, and glycerin may also be applied to the hands, or a dilute carbolic compress substituted. When the eruption is thick in the scalp it may be necessary to cut the hair short. The administration of salol in 10-grain doses every 4 hours is believed to modify the pustular stage. An attempt to combat the amount of suppuration by exposing the patient to red light, whereby actinic rays are cut off, is recommended by Finsen, but is said to prove too depressing. To mitigate the offensive odour which emanates from the skin, dilute carbolic lotions may be used (they also relieve the itching), or creosote may be vaporised in the sick-room. Starch poultices and alkaline washes are used for the removal of refractory crusts and zinc ointment applied. The eyes require special attention; they should be bathed with boric acid lotion at frequent intervals, and dilute nitrate of mercury ointment smeared on the edges of the lids. Should keratitis threaten, an ointment of atropine with yellow oxide of mercury should be applied.

Laryngitis calls for a steam tent and inhalations of benzoin or lysol. Circulatory failure is combated by the usual methods, and strychnine is useful as a nervous and respiratory stimulant. During decrusting and convalescence frequent warm baths are grateful, and quinine is a useful tonic.

Patients are to be regarded as infectious until the scabs are all separated and the skin quite healed.

VACCINIA

Vaccinia or cow-pox, a disease at one time very prevalent among cows, but now rare, is characterised by a vesicular eruption on the udders and teats. The vesicles, which are surrounded by an inflammatory areola, may by rupture form extensive ulcers. Abrasions on the hands of milkers may be accidentally inoculated from these lesions and they, in turn, may inoculate other cows in the herd. The hands of the infected milker show vesicles with surrounding induration, the axillary glands become swollen and there is some fever. Individuals thus inoculated are protected from small-pox, and Edward Jenner made practical use of this fact by inculcating the practice of deliberate vaccination and transference of the virus from arm to arm. In addition he demonstrated that those thus inoculated were refractory to subsequent inoculation with the virus from small-pox lesions, and milkers who had had small-pox did not catch vaccinia from the cows. But it appears that although vaccinia protects against small-pox, an attack of small-pox does not always protect against vaccinia. Apparently vaccinia is the more powerful antigen.

After long dispute, the question of the identity of cow-pox and small-pox has been settled by animal experiment in favour of Jenner's view that the two diseases are one and the same, small-pox virus being so modified by its transmission through the cow that its inoculation results only in a local lesion, a lesion which, however, affords a high degree of protection against small-pox. Vaccinia differs from small-pox, whether the latter be natural or deliberately inoculated, in that it has lost its infective character, and so can be used for purposes of vaccination without risk of propagating small-pox.

The histology of the vaccine vesicle is similar to that of the lesion of small-pox. It goes through the stages of papule, vesicle and pustule ; and loculation is produced by persistence of the remnants of vacuolated epithelial cells in the form of septa.

Professor Paschen has described minute " elementary bodies " as constant accompaniments of vaccinal lesions, and Ledingham has shown that these " Paschen bodies " are agglutinated by the sera of rabbits which have recovered from vaccinia. It is believed that these bodies are the filtrable virus of the disease.

For the purpose of vaccination vaccine lymph is prepared by the inoculation of healthy calves, the contents of the vesicles being collected and freed from pyogenic and other extraneous organisms by admixture with glycerine. This process of glycerinisation kills most of the adventitious germs, but leaves the virus of vaccinia uninjured. The lymph thus prepared is stored in capillary tubes at low temperature, and will remain efficacious for at least 8 months. Its use is preferable to the direct inoculation from human vaccine vesicles.

The operation of vaccination is carried out as follows : An area of skin over the insertion of the left deltoid muscle or on the outer side of the thigh is carefully cleaned with soap and water, and afterwards with ether. The contents of a tube of lymph are then ejected on to the cleansed area in 2, 3

or 4 separate portions, according to the number of insertions proposed. A ¼ inch scratch is made through each drop of lymph with a sterile lancet or sterile needle, care being taken to avoid drawing blood, and the lymph gently rubbed over the scratches with the instrument used. The scarified spots should be at least an inch distant from each other to avoid confluence. The lymph is given a few minutes for absorption, and any excess is removed with sterile wool. The scarified area is covered with sterile gauze. The whole procedure must be carried out with strict regard to asepsis. "Cross-hatching" is avoided.

If the operation is successful, inflamed areas appear at the sites of inoculation, and by the third day become distinctly papular. By the fifth day, small clear vesicles have formed which slowly increase in size and become depressed at their centres. By the eighth day the vesicles are large, sharply defined, and their inflammatory areolæ are confluent. From this time the contents become increasingly cloudy. The vesicles attain their full size by the twelfth day and collapse. By the tenth or twelfth day a brownish scab is forming. This after a time separates, leaving a depressed and pitted or foveated scar which at first is livid, but in course of time becomes dull white in colour. A more recent method of vaccination is by subcutaneous or intracutaneous injection of diluted vaccine. At present it is difficult to appraise its value.

The virus is distributed by the blood throughout the body. Headache, malaise and fever accompany maturation of the vesicles at the beginning of the second week; the axillary glands may become enlarged and tender and the spleen palpable. Sometimes febrile disturbance is noticed as early as the fourth day.

In revaccination the events are similar, but both the local and constitutional disturbances are less pronounced: sometimes they fail to appear at all. The lesions may run a very rapid course, aborting at the papular or early vesicular stage. Sometimes a slight itching and glandular tenderness are all that is observed.

Natural insusceptibility to primary vaccination is excessively rare, and at least three successive attempts should be made before insusceptibility is assumed.

Although infants can be vaccinated successfully in the first few weeks of life, under ordinary circumstances the best period is from the second to the sixth month. Revaccination is advisable after the seventh year and when small-pox is epidemic.

The degree of protection afforded against small-pox is in some degree proportional to the extent of the vaccinal lesion, and the resulting scars should, together, cover an area of not less than half a square inch. Hence the advice always to make at least two insertions and preferably four. The test of a successful scar is its depression and foveation. The period of immunity may be regarded as not less than 7 years. When vaccinal encephalo-myelitis is prevalent, vaccination by one insertion has been recommended.

Risks of Vaccination.—Fugitive erythemata, which are sometimes scarlatiniform, measly or urticarial, may appear about a week after vaccination; they resemble serum rashes. Erysipelas, septic infection and cellulitis sometimes result from the use of contaminated lymph or the lack of proper cleanliness at the operation or after. Under modern methods of glycerinisa-

tion and asepsis, these should not occur. There is no doubt, too, that syphilis has on rare occasions been conveyed by arm-to-arm vaccination. In such cases, the chancre does not appear before the fifteenth day, and is usually later. The calf being insusceptible to syphilis, the use of calf lymph has abolished this danger. Tetanus is another infection which has occasionally resulted, especially in hot climates. Tuberculosis and leprosy have also been cited as possible sequels, but with little or no proof. The addition of glycerine to the lymph kills the tubercle bacilli. The appearance of eczema and impetigo has been attributed to vaccination, as also a somewhat persistent form of anæmia. A rare sequel, to which attention has been drawn recently, is a form of encephalo-myelitis. Its greatest incidence has been in Holland, Great Britain and Germany, and has varied from 1 in 5000 to 1 in 100,000 vaccinations. The characteristic lesion is a focal, perivascular demyelinisation of nerve fibres, often associated with perivascular cuffing. It very rarely follows vaccination during the first year of life. Its chief incidence is after primary vaccination of children of school age or of adolescents. It is very similar to the encephalo-myelitis of small-pox and of measles. It sets in 7 to 12 days after vaccination, with headache, vomiting and paresis. These symptoms become aggravated, and delirium may pass into coma and death. In other cases the symptoms are more suggestive of meningitis, tetanus or lethargic encephalitis, with ocular palsies. The mortality may reach 50 per cent., but complete recovery is possible. Human serum, from a healthy donor who has been successfully vaccinated recently, or anti-vaccinal horse-serum, is the best antidote. The serum is given intrathecally or intravenously. The dose is 8–30 c.c., repeated if necessary. Repeated lumbar puncture is a valuable adjuvant.

Quiescent infection may be brought into activity and prominence by vaccination; this is the case with congenital syphilis and tuberculosis. Hence the advisability of postponing vaccination should the infant show signs of ill-health. Acute specific fevers are no bar to vaccination if necessary.

Very rarely the course of vaccinia is characterised by the appearance of a generalised vesicular eruption, the lesions appearing in successive crops, and passing through the stages of papule, umbilicated vesicle and crust. *Generalised vaccinia* of this type is usually febrile and occurs from 7 to 11 days after vaccination.

Accidental vaccinia is the term applied to fortuitous inoculation from a vaccinal lesion. Mothers are sometimes thus inoculated from their infants. The condition should be borne in mind. When occurring on the face, there is much œdema with swelling of the lymph glands, so that anthrax has been suspected. The vaccinated baby may also, by scratching, inoculate its own nose, cheeks or other parts of its body.

Protection afforded by Vaccination.—The immunity to small-pox which vaccination confers is not necessarily permanent. A child vaccinated in infancy should be revaccinated at the age of 7 years and again in adult life. Whatever their vaccinal condition, with the possible exception of those vaccinated within 2 years, persons coming into contact with small-pox should be revaccinated at once.

Since vaccinia has a shorter incubation period than small-pox, a person successfully vaccinated or revaccinated within 3 days of exposure to the latter disease will, in all probability, escape it. Ricketts makes the following state-

ment: "The period of incubation of small-pox, counting to the outcrop of the rash, may be taken as 14 days. If this period be divided into three intervals comprising 7 days, 3 days and 4 days, it will be accurate, in the main, to say that a successful vaccination done in the first period will wholly prevent the attack, done in the second will have more or less effect in modifying the eruption, and done in the third will merely add to the patient's troubles."

For a discussion of the evidence in favour of the practice of vaccination in the prevention of small-pox, the student is referred to the larger treatises.

CHICKEN-POX

Synonyms.—Varicella; Glass-pock; Water-pock.

Definition.—An acute infective disease, characterised by a rash which tends to appear in successive crops, each lesion passing rapidly through a papular stage to one of superficial vesiculation and subsequent partial pustulation. The lesions then desiccate and scab.

Ætiology.—Chicken-pox is universally prevalent and highly infectious. One attack usually affords complete protection, second attacks being extremely rare. It is mainly an affection of middle childhood, being uncommon after 10 years of age, but adults may contract it, and infants are not completely immune. Season and climate are not known to exert any influence on its incidence. It affects both sexes. Infection is in most cases direct by droplet spray, but articles of clothing may remain infectious for a considerable time, and the disease is sometimes carried by a healthy intermediary. The dried scabs can communicate the disease, probably by ingestion or inhalation. Like small-pox, chicken-pox is inoculable from the vesicles—but not easily. Convalescents from acute diseases, particularly from measles, diphtheria and scarlet fever, are believed to be peculiarly susceptible to chicken-pox. The disease occurs sporadically or in the form of limited outbreaks. The infective agent is unknown, but the association with herpes zoster lends support to the view that it may be a filtrable virus, identical with the neurotropic virus of that disease.

Pathology.—Micro-organisms occur in the pocks, and particulate bodies have been described similar to those seen in vaccinia and small-pox. Pure suspensions of these particulate or elementary bodies are agglutinated by the serum of convalescents from varicella or herpes zoster. The inflammatory lesions are more superficially situated in the skin than those of small-pox; but the process of vesiculation is similar. Loculation is indistinct, and umbilication exceptional. When the clear vesicles become clouded, but rarely before this, polynuclear and mononuclear cells are found in their contents.

Symptoms.—*Incubation period.*—This is usually a fortnight or a little more; but extremes of 11 to 23 days are mentioned.

In childhood the appearance of the eruption usually constitutes the first sign, and is taken to indicate the first day of the disease. In adults slight pyrexia and sometimes headache, shivering, and even pain in the back may precede the eruption for 48 hours. In exceptional cases, mostly in children, vomiting and convulsions have occurred.

Prodromal rashes are not very uncommon. An erythema, either patchy

or uniform, which may be punctate, sometimes precedes the eruption for some hours, and may be mistaken for scarlet fever; it avoids the face, does not blanch by the Schultz-Charlton test, and does not desquamate. The incipient papules of chicken-pox can sometimes be recognised in the erythema. Less frequently the prodromal rashes are measly or urticarial.

The eruption of chicken-pox appears first on the trunk, but soon spreads to the face, the scalp and the proximal parts of the limbs. Sometimes it is on the face that it is first noticed. Occasionally, and sometimes primarily, the eruption invades the mucous membranes, especially the fauces, soft palate and the pharynx. The spread of the rash does not conform to the orderly progress of small-pox, it appears in several crops on successive days; these may come out for 2 or 3 days in mild cases, for a week or more in those which are severe. The total number of lesions may be anything from a few to some hundreds. They are thickest on the trunk, especially on the back, and next to this on the face and in the scalp. They tend to invade the limbs from above downwards, being sparse and often small on the distal portions; a few vesicles are occasionally seen on the palms and soles. The axilla does not escape as in small-pox, and it is unusual for the rash to show an especial incidence over ridges or pressure points. Various forms of skin irritation may determine a local profusion of the rash.

The lesions are in turn macular, papular, vesicular and mildly pustular. The macules are very transitory, soon becoming rounded or ovoid papules of a pinkish colour and slightly salient, something like the rose spots of typhoid, or larger. Vesiculation rapidly ensues, and is complete in 24 hours or a little more. The vesicles seldom exceed a third of an inch in diameter. They look like translucent droplets, lying on rather than in the skin. An areola may or may not be present. On the scalp, forearms, hands and feet they may appear deeper, and show some hardness. Some assume oval or irregular outlines, especially when lying near creases or folds of the skin. On maturity the vesicles take on a pearly hue. When punctured, most of them collapse entirely, and umbilication is rare. Confluence of adjacent vesicles hardly ever occurs. Owing to its itchiness, the rash is often infected by scratching or rubbing, and then the lesions become larger and more inflamed. Otherwise the vesicles dry up into superficial brown scabs in a day or two, which on separating leave slight pink stains, but no appreciable pitting.

The appearance of the eruption in successive crops leads to the presence at the same time on a given area of skin of lesions in all stages of development, *i.e.* papules, vesicles, small pustules and scabs. On mucous membranes the vesicles soon rupture and leave shallow grey ulcers, often with red areolæ.

Slight pyrexia usually accompanies the appearance of the rash. Some cases are apyrexial throughout. Rarely the temperature rises as high as 103° or 104° F. Successive crops of spots may be accompanied by successive exacerbations of fever. Constitutional symptoms as a rule are absent.

Varieties.—Chicken-pox varies much in intensity. It may be so mild that only one or two pocks are recognised. As mentioned above, sharp invasive symptoms may mark its advent in the adult. There are three special varieties of the severe disease: (1) *Varicella bullosa*; (2) *Varicella gangrenosa*; and (3) *Varicella hæmorrhagica*. In *V. bullosa* the vesicles rapidly form large blebs, which on rupture leave painful raw surfaces. *V. gangrenosa*

is seen in debilitated children and those recovering from scarlet fever; large dark crusts form, and on separation reveal ulcers which may spread on the surface and in depth with great rapidity. Constitutional disturbance is severe, and pulmonary complications often supervene. Infection of the lesions with hæmolytic streptococci or virulent strains of the diphtheria bacillus should be suspected. *V. hæmorrhagica* is rare; hæmorrhages occur into the vesicles and intervening skin, and bleeding sets in from the mucous membranes. It is very fatal. Bleeding confined to the vesicles is not so serious.

Complications.—Laryngitis or slight bronchitis is present in some cases. Pocks on the conjunctivæ, vulva or prepuce may give rise to troublesome symptoms. Accidental septic rashes sometimes appear in the eruptive stage. Acute nephritis and arthritis are exceptional.

Nervous complications are very rare and usually benign. They are attributed to encephalo-myelitis, and chiefly affect children, usually occurring during the second week of the infection. Rarely they precede the eruption. The onset is acute and febrile; it may be accompanied by vomiting, vertigo and convulsion. Ataxia and tremor are more common than motor paralysis. With spinal lesions the picture may be that of a transverse myelitis. Optic neuritis, ophthalmoplegia and, very rarely, peripheral neuritis have also been recorded. In most cases recovery has ensued.

Herpes zoster is closely akin to chicken-pox. The zoster eruption may be preceded, accompanied, or followed by a vesicular rash indistinguishable from chicken-pox. Herpes zoster may also give rise in contacts, mostly children, to typical chicken-pox after an incubation period of from 12 to 21 days, and chicken-pox may follow inoculations from zoster vesicles. Conversely, for chicken-pox to give rise to herpes zoster, is a much less common event, which usually occurs in adults.

Diagnosis.—A mild or modified case of small-pox may erroneously be supposed to be chicken-pox, or chicken-pox with a profuse eruption and constitutional, or the rare hæmorrhagic, symptoms may be supposed to be small-pox. The differential diagnosis, in which the distribution of the rash is of primary importance, is considered in the article on small-pox. Here it may be stated that in a patient under 10 years of age, with well-foveated vaccination scars, a profuse eruption is generally chicken-pox, whilst a scanty eruption with well-marked invasive symptoms is more likely in these circumstances to be modified small-pox.

The erythematous prodromal rash may simulate scarlet fever; but other signs of this disease are wanting, and the chicken-pox eruption appears within 24 hours.

Certain skin diseases characterised by vesicles or bullæ may be mistaken for chicken-pox. These include insect bites, scabies, acne, impetigo, papular urticaria, pemphigus and erythema multiforme. Differential criteria are prolonged duration, recurrences, distribution, absence of fever, and of lesions in the mouth.

A varicella-like type of syphilide is known. It usually affects the trunk, is much more persistent, and is accompanied by other evidence of its nature.

Prognosis.—Death is very rare. The gangrenous form may prove fatal to debilitated children, and the rare hæmorrhagic form is said by most authorities to have a very bad prognosis.

Treatment.—Although most infectious in the pre-eruptive and early eruptive stages, patients should be isolated until every scab has separated—usually a period of 2 or 3 weeks. They should be confined to bed during the eruptive period. Skin irritation may be allayed by mild dusting powders, and it is sometimes advisable to fix the arms in light splints. It is rarely necessary to cut off the hair. Inflamed pocks may need fomentation with boric acid. Crusts which re-form may be removed by starch poultices and zinc or mercurial ointment applied. Gangrenous varicella may be treated by the use of scarlatinal and diphtheria anti-toxin, and drugs of the sulphonamide group.

When discharging patients particular attention should be paid to the scalp, as scabs may remain entangled in the hair. It is doubtful if lesions which have crusted several times are still infectious. The quarantine period for contacts is 3 weeks.

MUMPS

Synonyms.—Epidemic Parotitis; Infectious Parotitis.

Definition.—An acute infectious disease, characterised by swelling of the parotid, and sometimes of the other salivary glands, accompanied by constitutional disturbance which is usually mild. With the exception of orchitis, complications are infrequent, and a fatal termination is exceedingly rare.

Ætiology.—Mumps is endemic in most large centres of population throughout the civilised world. No climate is adverse and no race is immune. Children and young adults of both sexes are those usually attacked; but no age is entirely exempt, although the disease is rare in infants and in the aged. The mother has transmitted the disease to the fœtus *in utero*.

The malady usually appears during the winter or spring months. Outbreaks are generally localised, and often limited to particular schools, business houses or barracks. Infection is direct from patient to patient; but is sometimes conveyed by an apparently healthy intermediary, or by fomites. Epidemics of mumps may follow outbreaks of measles.

Pathology.—Mumps is attributed to infection by a neurotropic filterable virus. Invasion of the nervous system is thought by some to occur prior to invasion of the salivary glands. An alternative view is that a primary septicæmia is followed by localisation of the virus in susceptible organs. The disease can be passed to cats and monkeys by bacteria-free filtrates of saliva or puncture fluid from the swollen glands, and has been re-transferred from monkey to man. Older views were that certain diplococci or spirochætes were the infecting agents.

An interstitial inflammation is said to occur in the affected salivary glands, but parenchymatous inflammation is described in the case of the pancreas and the testicle.

Symptoms.—The incubation period is 3 weeks; but extremes of 14 and 35 days, or even 37 days, are admitted. A swelling of the parotid gland is usually the first indication of the malady, but this may be preceded for a day or two by pain and stiffness in the region of the masseter muscle, or by such prodromal symptoms as feverishness, shivering, and sore throat. Sometimes a meningeal reaction marks the onset (*Cerebral Mumps*).

The parotid swelling is at first unilateral, and commonly appears on the left side. It may increase for 2 or 3 days, forming an ill-defined, elastic swelling, which obliterates the sulcus between the mandible and the mastoid process, lifts the auricle away from the head in a characteristic manner, and extends forwards on the surface of the masseter. Only rarely is the skin over the gland either reddened or œdematous. The swelling subsides after a few days, sometimes very quickly, but a distinctive and, when present, highly diagnostic feature is the occurrence, 24 or 36 hours after onset, of swelling in the other parotid region, sometimes with fresh febrile disturbance ; or the submandibular and sublingual glands may be attacked. The interval between the invasion of the two parotid glands may extend to 4 or 5 days, or even longer ; but sometimes they are attacked simultaneously. Sometimes, too, the submandibular glands become swollen first, in which case palpation with one finger in the mouth and another below the jaw will reveal the acorn-like swelling. The parotid may escape, or may swell in its turn. When multiple bilateral glandular swellings are present the features become much distorted.

Moderate pyrexia (101° or 102° F.) may accompany the onset and persist for a day or two ; but the attack is often afebrile and the pulse rate hardly quickened. On rare occasions constitutional disturbance is severe, the temperature rising to 104° or 105° F., with delirium and circulatory depression.

The inflamed parotid gland may cause great pain on attempts to separate the teeth, to chew or to swallow. The secretion of saliva is often defective, but in some excessive salivation is noticeable. Injection of the orifices of the salivary ducts, pharyngitis, faucial congestion and even tonsillitis are sometimes observed at the height of the attack. Enlargement of the cervical lymph glands rarely occurs. Mumps may appear in so mild a form as to be hardly noticeable. At times the only salivary gland affected is the submandibular (submaxillary mumps), and occasionally orchitis is the sole manifestation of the disease. Invasion of the lachrimal gland has occurred.

With rare exceptions the swellings caused by mumps neither suppurate nor persist, although, occasionally, the parotid is said to be several months in resolving. Relapse occasionally occurs.

During the period of glandular swelling the blood usually shows a moderate leucocytosis, a characteristic feature being a relative and absolute increase in the number of lymphocytes. The supervention of orchitis does not invariably alter the blood picture, although, according to some authorities, it may give rise to an increase in the number of polynuclear cells.

Complications.—*Orchitis* occurs in 15 to 30 per cent. of the males. It affects boys about the age of puberty and young adults ; in childhood it is rare. Sexual over-activity is held to be a definite predisposing factor. The seventh or eighth day of illness is the usual time of onset ; but it may appear 2 or 3 weeks later. In some instances orchitis precedes the inflammation of the salivary glands. The condition is really an epididymo-orchitis. Where surgical attempts have been made to relieve tension by decapsulation or incision, effusion has been found in the tunica vaginalis, the testis engorged, and the epididymis deep red. The onset is characterised by pain in the testis, which soon becomes swollen. Delirium, vomiting, collapse and considerable fever may accompany the testicular inflammation. The temperature may rise abruptly to 103° or 104° F. Fortunately the complication is usually one-

sided, but in 10 to 20 per cent. of cases the other testicle is attacked in turn. Orchitis may be accompanied by œdema of the scrotum, swelling of the spermatic cord and enlargement of the inguinal glands. Exceptionally a urethritis accompanies the testicular swelling. Subsidence of orchitis within a week is the rule, the temperature falling rather abruptly. Suppuration is very rare; but relapse sometimes occurs. When bilateral orchitis occurs before puberty the development of the individual is usually checked; rarely feminism has been reported. In the adult, even when both testes appear atrophic, spermatogenesis may return after many months.

In the female, corresponding complications are ovaritis, shown by ovarian pain and tenderness, inflammation and œdema of the vulva and mastitis. The latter has also occurred in the male.

Pancreatitis is a much less common complication than orchitis. It should be suspected when acute abdominal pain, fever, vomiting and epigastric tenderness, occur as sequels to the parotid swelling, which under these circumstances may show a rapid subsidence. Sometimes the swollen pancreas may be felt, but often its presence is masked by abdominal rigidity. The bowels are constipated, the stools may be fatty, or even contain blood. The urinary diastase is increased, and glycosuria may occur. The blood sugar may be raised. Jaundice is rare. The onset may be accompanied by alarming collapse. Fortunately recovery has occurred in most cases. Diabetes as a sequel to mumps is very exceptional. It should be noted that in mumps a raised diastatic index may occur without clinical evidence of pancreatitis, and is attributed to infection of salivary glands.

As regards the *nervous system*, symptoms of meningo-encephalitis may occur towards the end of the first or during the second week, and have even been known to precede the appearance of the glandular swellings. Sometimes on recovery such disabilities as aphasia, hemiplegia, monoplegia or ataxia persist. Rarely a general paralysis of the limbs with loss of deep reflexes, attributed to peripheral neuritis, occurs. Weakness of the muscles supplied by one facial nerve rarely accompanies the parotid swelling.

Acute mania and other forms of insanity are rare sequels.

An excess of lymphocytes may be found in the cerebro-spinal fluid, and is not uncommon during the first fifteen days of mumps, even in the absence of definite meningeal symptoms.

Certain affections of the *organs of special sense*, although uncommon, deserve mention on account of their importance. Quite apart from deafness, due to the occasional occurrence of otitis media, true nerve deafness may occur unaccompanied by signs of middle ear disease. The deafness is of sudden onset, and when accompanied by nausea, vomiting, tinnitus and inco-ordination it is attributed to hæmorrhage or exudation within the labyrinth; but it may occur without any labyrinthine symptoms. Fortunately the deafness is usually unilateral, for it is incurable.

Papillœdema and optic atrophy with loss of vision are other important sequels. Iridocyclitis, paralysis of certain extra-ocular muscles and loss of power of accommodation may also at times ensue; these mainly terminate in recovery after a variable time.

Among other possible complications may be mentioned epistaxis, bronchitis, pneumonia, pericarditis and arthritis. Albuminuria is not uncommon and nephritis sometimes occurs as late as 4 or 5 weeks after the salivary

swellings; uræmia has been responsible for death in rare instances. Gangrenous appendicitis has also been noted.

Suppuration in the parotid gland, gangrene of the gland, cellulitis of the neck and floor of the mouth, œdema of the glottis, and suppuration of the cervical lymph glands are very rare occurrences, which are generally attributed to superadded septic infection. Relapses, characterised by a recurrence of the glandular swelling after a distinct interval, are not very uncommon. Although one attack of mumps usually protects the individual for life, second attacks are not unknown.

Diagnosis.—In the presence of an epidemic this presents little or no difficulty; but the true nature of the infection may be overlooked when the parotid swelling is insignificant, or when the disease primarily affects the submandibular or sublingual glands, or again when orchitis or even pancreatitis constitutes the first, and perhaps the only, manifestation.

Parotitis, usually unilateral, and attributed to ascending duct infection, is a well-known complication of certain fevers, and of some abdominal diseases; but it also may be primary and assume a recurrent form. This is distinguished from mumps by the circumstances under which it occurs, and by the fact that it is not contagious. It generally ends in suppuration, and is accompanied by a polynuclear leucocytosis. Swelling of the salivary glands may follow the administration of certain drugs, such as iodide of potassium and pilocarpine.

A painless enlargement of the parotid and lachrymal glands, of great chronicity, occurs in Mikulicz's disease. In uveo-parotid fever irido-cyclitis accompanies the parotid swelling.

Inflammatory swelling of the higher cervical glands, especially when accompanied by peri-adenitis and œdema, may be mistaken for mumps. Swelling of this character occurs in certain cases of diphtheria, and also in scarlet fever. Careful attention to the history, proper examination of the fauces, and search for rashes should eliminate this error. Enlargement of the pre-auricular lymph gland due to lesions about the nostrils and angle of the mouth, and the swelling caused by periostitis of the lower jaw, or otitic infection of a zygomatic air-cell, may superficially resemble inflammation of the parotid.

When the submandibular and sublingual glands alone are swollen the distinction from lymphadenitis may be difficult. In such cases extension to the opposite side indicates mumps, as also does the transitory character of the swelling.

In glandular fever, which is an acute infective adenitis of the cervical and other lymphatic glands, the salivary glands are not involved.

Prognosis.—The mortality from mumps is remarkably low. The majority of deaths occur in children under 5, especially in infants, usually from some complication. Cases of mumps in pregnancy may also prove fatal.

Treatment.—Mumps is infectious for 2 or 3 days before the swelling appears, and isolation for not less than 2 weeks from the onset is advisable, provided that one clear week has elapsed since the subsidence of the glandular enlargement. Contacts should be removed from exposure and either isolated for 28 days or supervised from the fourteenth to the twenty-eighth day, unless they have already had the disease. Thirty c.c. of whole blood or 15 c.c. of serum of convalescents, if given on first exposure, seems to prevent infection.

Attenuated attacks are difficult to produce, but see also remarks under measles (p. 141). On account of the liability to orchitis, it is better to have mumps before puberty than after.

The patient should be isolated and confined to bed. The incidence and severity of orchitis are said to be less in those who are not allowed to get up until the time at which this complication usually appears is past. Foods which need no mastication are indicated during the acute stage. The mouth should be kept clean. Pain may be relieved by local applications and acetyl-salicylic acid. The inflamed testicle should be enveloped in cotton-wool and suspended or supported by a small pillow. If pancreatitis be suspected, fomentations may be applied to the abdomen, small doses of opium administered, and the diet strictly restricted to fluids. Delirium and pyrexia are met by sponging, wet-packs or the ice-cap. Repeated lumbar puncture is beneficial in meningo-encephalitis.

CHARLES R. BOX.

INFLUENZA

Definition.—An acute infectious disease of short duration, existing in pandemic and epidemic form, with sporadic outbreaks. It is characterised by sudden onset, pyrexia, headache, pains in the back and limbs, and a tendency to inflammatory complications in the respiratory system.

Ætiology.—Are the protean features of disease which are at present included in our conception of influenza all manifestations of the same *materies morbi*? Are there influenzas rather than influenza? What causative factors determine the pandemics of the disease during which the case-incidence rises so rapidly and so enormously? What is the association between benign influenzal catarrhs of endemic and sporadic occurrence and the pandemics which decimate whole races of mankind? These are questions which have baffled epidemiologists and bacteriologists for many years, nor did the exceptional opportunities for observation and research afforded by the pandemic of 1918–19 serve entirely to answer them.

We are ignorant of the reasons why a state of relative quiescence in regard to the incidence of the disease—scattered sporadic cases and mild epidemics—suddenly blazes up into a devastating pandemic. We know that when this conflagration arrives the disease becomes very highly infectious in character, that its virulence is enormously increased and that the usual close association with catarrhs and seasons and latitudes and lowered general resistance is no longer observed. Age gives no security at such times; witness both the high case-incidence and high case-mortality in young adults during the pandemic of 1918–19.

A previous attack of the disease gives little or no protection; according to some authorities the reverse is the case.

In the matter of its relation to other catarrhal states the absence of definite criteria makes it impossible to be precise in diagnosis. It is only in the presence of a severe and widespread outbreak that the guide of probability is of assistance in this respect.

Andrewes and his co-workers at the National Institute for Medical Research in 1933 isolated from the nasopharyngeal discharge of influenza patients a

virus which is capable of infecting ferrets. When human influenzal garglings are dropped into the noses of ferrets they become ill in 48 hours and the disease has been transferred from the experimental animals to the experimenter. Further, they have shown that patients who have had influenza recently develop antibodies in their blood which kill, or inactivate, the virus. Neutralisation tests with antisera prepared from human strains prove that different serological varieties of the virus exist. Pfeiffer's bacillus is to be regarded as the commonest secondary invader of the infected tissues. Next to Pfeiffer's bacillus, the micro-organisms most commonly found in association with the disease are streptococci of the hæmolytic kind, pneumococci, *M. catarrhalis* and *Staphylococcus aureus*. It seems certain that many of the most serious and fatal cases owe their lethal character to virulent streptococci. Pfeiffer's bacillus occurs in cases of disease quite other than clinical influenza—septic endocarditis, sinusitis and meningitis. The bacillus is of very small size, is Gram-negative in staining reaction, grows with difficulty on ordinary media and has low vitality outside the human body. A special feature seen in regard to it is the fact that, when present in acute cases of influenza, it usually occurs in enormous numbers in the infected tissues and their secretions.

Symptoms.—So far as can be judged the incubation period is, with considerable constancy, something from 24 to 48 hours. A marked feature of the disease is the abruptness of the onset. So abrupt is it at times that the victim is striken down, as it were, in the street, and, from being quite well he is, within a few hours, prostrated and already suffering the maximum discomforts of the disease. The temperature rises rapidly; there is often a rigor. The chief symptoms are racking headache, intolerable aching pains in the loins and limbs, dryness and irritable redness of the mouth and fauces, and a distressing dry cough. An erythematous rash is not uncommon.

Although the symptoms are protean, it is customary to describe certain types of case that are frequently met with, dependent largely upon the particular tissues and functions which suffer the chief results of the infection. It is to be noted that different outbreaks of the disease are prone to be characterised by different clinical types, as also by differing degrees of severity.

1. *The febrile type.*—In this variety of the disease the chief features are pyrexia, with associated malaise, headache, pains in the back and limbs and a moderate degree of catarrh of the upper air-passages. In many cases this type differs only from the "common cold" in its more abrupt onset, its higher degree of pyrexia, its disproportionately severe prostration and its relatively "dry" form of catarrh. The eyeballs are often painful, with some conjunctivitis, and the fauces are often red and slightly œdematous. Cough is often present, with few or no associated pulmonary signs. The pyrexia lasts for a variable time, usually 4 to 6 days; the temperature chart may show two peaks in the 24 hours. It is unusual to see the fever prolonged past the eighth day without some focal complication, generally pulmonary. Defervescence is quite frequently by crisis, but this is by no means the rule.

2. *The respiratory type.*—This is the form of the disease which is most prevalent in pandemics, and, when severe, it is the form to which the mortality is chiefly due. Somewhere about the fourth day of the disease it becomes obvious that the catarrhal process is growing troublesome, with more definite

involvement of the larynx, trachea and bronchial tract. A dry catarrh of the larynx and trachea, with pain and distressing cough, may constitute the main feature of the disease. In many cases the temperature falls about the third or fourth day, to rise again concurrently with a definite exacerbation and extension of the catarrh. The respiratory involvement does not tend to remain localised as a bronchitis, but involves the lung tissue, leading to a bronchiolitis and, in many cases, an alveolitis also. Then ensue the signs of acute pulmonary congestion which are so characteristic of the disease, and cause so much anxiety for fear of untoward developments. The respiratory manifestations of influenza infection extend from laryngitis and tracheitis through bronchitis to lobular and lobar pneumonia and pleurisy, both "dry" and with serous or purulent effusion. But the dominant feature, rarely absent in any really severe case, is a condition of capillary bronchitis with intense pulmonary congestion. This may be unilateral or bilateral, is more often basal than apical, but is not seldom universal. The physical signs are copious fine râles (crepitation), with impaired vesicular sound, and, less often, impaired percussion tone. This condition may well be termed the essential lesion of the disease, for even when actual consolidation of the lung is present, this is quite often an incident by comparison, and if the patient dies, he dies with the consolidation rather than of it.

Cough is usually a very troublesome symptom in this type of the disease, and is often quite independent of the need to expectorate. The sputa vary considerably. They may be quite absent, even in cases where there is widespread lung congestion. When present they are generally of a kind that corresponds with the nature of the chief lesion, whether tracheitis, bronchitis or pneumonia. Two special kinds of sputa are very typical of influenza, and they are seen frequently during epidemics. (*a*) Bright, pink, frothy mucus, sometimes produced in large amount, it may be as much as a pint in 24 hours. This rose-red mucus results from acute inflammatory œdema of the lung. It may be expelled involuntarily during cough and sometimes it spurts from the nostrils. (*b*) Tenacious mucus, less viscid than in lobar pneumonia, and more copious, differing also in colour which is of several hues—red, brown, saffron and various shades of green, all of these being occasionally present at the same time. Seen in a white earthenware vessel these sputa are very striking and in a high degree diagnostic.

3. *The malignant type.*—This severe and very fatal form is almost confined to pandemic or to epidemic periods. The patient is gravely ill from the onset, or soon after, with intensely toxic symptoms, cyanosis of a peculiar character ("heliotrope cyanosis") and rapid development of heart failure before focal manifestations have time to show themselves—unless it be the presence of copious fine râles of the kind referred to in (2). The duration of this type of case varies from 48 hours up to a week, and no measures of treatment, however prompt, serve to avert the almost certain issue. It is asserted by reliable observers that death may occur even within the first 24 hours from the onset.

4. *The gastro-intestinal type.*—More strictly, perhaps, gastric and intestinal types. These types are less common in pandemics and epidemics than in small endemics and in sporadic cases. The gastric cases are quite common, and some of the milder endemics seem to "breed true" to a remark-

able degree in this respect, leading to a very constant clinical picture of an illness with acute, even abrupt, onset, vomiting, marked anorexia, epigastric and umbilical tenderness, and general prostration. Considerable difficulty often arises in diagnosis (see p. 171), even when there are several cases of a similar kind prevalent.

Jaundice of the catarrhal kind is not very uncommon as a complication. Some of the intestinal cases give no less difficulty, and when severe the likeness to typhoid fever is sometimes very close indeed. Tympanites, diarrhœa and enterorrhagia, associated with continued high fever and a leucopenia, may deceive the very elect.

5. *A nervous type* has been described, but it is perhaps more correct to say that a variety of nerve symptoms may arise both during and after the acute infection, rather than that a recognisable clinical picture is produced (see p. 171).

Complications and Sequelæ.—These are both numerous and important. Indeed, if we except the malignant cases and the very severe respiratory cases occurring during pan- and epi-demic periods, it may be said that the importance of the disease lies more in its complications, and perhaps still more in its sequels, than in the stage of infection proper. For convenience these disabilities may be grouped as follows:

1. *Respiratory.*—The main extensions of the catarrhal process have been already referred to, as also has the occurrence of pleurisy. Sinusitis may be mentioned here; it is both common and troublesome. Otitis media also occurs. Asthma sometimes appears for the first time in a patient's life after influenza, and the age of the sufferer may be much more advanced than is usual with asthma generally. Pulmonary tuberculosis not seldom shows itself also for the first time in the same association. The most frequent sequel of all, however, is the maintenance of a state of chronic congestion or bronchiolitis at one base or both bases of the lung. This condition, which may persist for years, ebbing and flowing with the seasons and with the occurrence of intercurrent catarrhal infections, may prove the starting point of bronchiectasis.

2. *Circulatory.*—Perhaps the most serious complication and sequel is referable to the heart. Some degree of dilatation is very common during a severe attack of the respiratory type, and this condition is apt to prolong convalescence in a very tedious fashion. In some cases a bradycardia due to heart block has been observed: the prognosis in this condition is good. But a much more common form of heart disability is that which arises insidiously after the patient begins to resume his usual routine of life. He is the subject of palpitation, præcordial distress and a sense of undue fatigue with slight effort. In women this state of things is complicated often by nervous symptoms, and attacks of breathlessness and a sense of impending collapse are quite common. As there is frequently in addition a considerable degree of true nervous prostration with mental depression it becomes exceedingly difficult to decide to what extent the heart is really affected. Physical signs in these cases are wholly inadequate; quite often they are absent altogether. Although, with care and encouragement, many of these cases get quite well after a time, a large number unfortunately become more or less permanent "heart invalids." It is not clear what is the exact pathology of the "influenzal heart," but it is perhaps near the truth to consider it in

the main a toxic myocarditis; though to what degree it is the nervous mechanism, and to what degree the heart muscle, that suffers we cannot say.

Vasomotor troubles are not uncommon and often complicate the heart condition. Phlebitis may occur.

3. *Nervous.*—The most common complication is the intense depression from which the patients so frequently suffer. In a few cases this leads to actual mental instability and, in fewer still, to suicide. The depression may continue for a long time after the acute illness is over. So common a symptom is it that patients themselves often consider the nature of a recent febrile illness to be definitely established as influenza because of this resultant depression. And they are probably in most cases correct. The headache, which is another very constant accompaniment of the illness, may be so severe as to raise the question of meningitis; it quite commonly leads to some delirium in patients whose nervous system is, in health, none too stable.

A true meningitis occurs now and again with *H. pfeiffer* in the cerebro-spinal fluid and a clinical picture that is unequivocal. Encephalitis and myelitis are described, but here, again, the diagnosis—from epidemic encephalitis—must always be a difficult matter.

Many other nerve conditions are described by authors. Perhaps neuritis, of both single and multiple types, is the most common. One of us (H) has seen a condition indistinguishable from paralysis agitans follow a severe attack, which ended in complete recovery after several months.

Diagnosis.—During pan- and epi-demics the diagnosis is, as a rule, not difficult, especially when the case if very severe. "Filming" the sputa in a case of the respiratory type is a valuable aid to diagnosis. If the highly characteristic condition of bronchiolitis with copious fine râles referred to on pp. 168–169 be present in a febrile illness with nerve prostration and general toxæmia, the diagnosis is fairly certain.

The gastric and intestinal cases, and especially the latter, present more difficulty than do the respiratory cases. The gastric cases resemble food-poisoning not a little, and appendicitis may require careful consideration in patients with abdominal tenderness, pain and vomiting, of acute onset. From typhoid fever a severe intestinal case with hæmorrhage and enlarged spleen can only be distinguished by absence of agglutination and negative blood culture. A leucopenia is present in both diseases.

The diagnosis of milder cases of influenza, if occurring in sporadic fashion, is frequently a frank admission that it is well to give the patient and his friends a label to his disease. There are so many causes of an acute febrile illness with malaise and slight catarrh that exact diagnosis may not be possible.

A word of warning is perhaps necessary in respect of diseases known to be prevalent coincidentally with outbreaks of influenza. Thus, true pneumococcus pneumonia, whether lobular or lobar, is not infrequently called influenzal when this latter disease is epidemic. Of greater importance is the fact that waves of incidence of influenza and poliomyelitis and encephalitis sometimes concur. If the practitioner's attention is bent only upon the former disease he is apt to put down to it certain serious nerve lesions that really belong to the latter.

Treatment.—PROPHYLACTIC.—As we do not know the factors leading to

the production of influenza epidemics we do not know how to prevent them. When they arrive we can, to some extent, control them by efficient quarantine, by early diagnosis and notification and by a proper system of hospitalisation, adequate to the peculiar features presented by the disease. In regard to individual prophylaxis it was formerly held that to keep generally "fit" was a good protection against infection. But recent experience does not confirm this view: influenza attacked the strong as well as the weak; indeed, the robust young adult fell a victim by preference, though this may have been partly because he was more open to infection by virtue of the conditions of his life. The age-mortality as well as the age-morbidity during the 1918-19 pandemic seemed to make it clear that some method of specific immunisation is essential before we can hope to protect against infection. The available vaccines for protective inoculation aim at raising resistance against the secondary infections. Regarded in this light they are rational. So far the virus is not available for specific prophylaxis.

CURATIVE.—1. *General Measures.*—With the onset of symptoms the patient is put to bed and is kept there until the temperature has reached normal and has remained there for 48 hours. He is only allowed up if examination of the heart and lungs, and a review of his general condition, reveal nothing abnormal. If the attack has been severe, the patient should be induced to remain in bed for a week after the temperature is normal, because relapses are common, and are often more dangerous than the original attack. This rule of practice should certainly have no exception in the case of patients over 50 years of age.

The largest available room is chosen, and the bed is placed well away from the walls. Blinds, curtains and screens are dispensed with, and the windows are kept open day and night. The room temperature is kept as near to 60° F. as possible. If the ideal of free ventilation with warmth cannot be secured in the room, then warmth must be sacrificed rather than ventilation. Neglect of fresh air not only seriously prejudices recovery in the event of pulmonary complications, it undoubtedly tends much to induce them. It is probably the most important point in the general treatment.

The diet is confined to warm fluids, given frequently, but easily digested solids are allowed if the stomach tolerates them; efforts at "feeding up" the patient are to be deprecated. Unless the patient is elderly, alcohol is not needed in the early stages of the disease when there are no complications. The bowels are made to act thoroughly by a double dose of the patient's customary aperient. If he has none, he is given ¼-grain doses of calomel every hour for 4 doses, and this is followed by a saline draught. The patient is sponged all over with warm water twice daily.

2. *Drugs.*—There is no drug which acts as a specific. Aspirin and Dover's powder in 10-grain doses may be given together as early as possible and may be repeated once or twice every 6 or 8 hours. This may be followed by a simple diaphoretic mixture. The sulphonamides are only of service when secondary infections are present, and especially when these are of a pulmonary nature.

3. *Treatment of Symptoms.*—If the headache is severe, phenacetin gr. 10 with caffeine gr. 2 may be given 4-hourly for 4 doses. If the stomach gives trouble, and the tongue is foul, sod. bicarb. and sod. sulphocarb., of each gr. 10, with glyc. acid. carbol. min. 10, may be given 6-hourly with the

feeds, well diluted. For vomiting, all feeds are reduced to a minimum, or omitted entirely for 48 hours, giving sips of hot water only, with minim doses of liq. iodi mitis in 60 min. of water hourly for 6 or 8 doses, and one pint of normal saline is introduced into the bowel two or three times during the period of starvation.

Distressing and persistent cough is often the most difficult problem. Local applications to the chest are often of service. If the origin of the cough is irritability of the upper-air passages inhalations of tinct. benzoini co. 4 parts, with menthol or eucalyptus 1 part, are useful. Failing this a spray containing chlorbutol (chloretone) and menthol, 2 per cent. of each in liquid paraffin, may be used to the nose and throat. In the "essential cough" of the disease, syr. cocillanæ co., syr. codeinæ and tinct. terp-heroin. co. are of some value. In intractable cases relief may follow syr. chloral min. 30, ammon. brom. grs. 10, with ext. glycyrrhiz. liq. min. 20, etc., in 4-hourly doses for 4 doses.

Insomnia calls for a general review of the whole programme—ventilation, control of pyrexia, posture, food, stimulants, etc. Failing attention to these things, a sedative draught of ammon. brom. grs. 20 and tinct. valern. min. 20 may be tried; if not successful, min. 120 doses of paraldehyde, with tinct. quillaiæ and tinct. aurantii to cover its unpleasant taste. Failing this, again, chloral and bromide may be given, since drugs of the barbitone group are better avoided.

4. *Treatment of more Severe Cases and of Complications.*—(*a*) *Intensely toxic cases, with hyperpyrexia.*—Attention to good ventilation should be redoubled. The thermometer and not the patient's sensations must be the guide to the amount of bedclothes. "Cradling" is often very useful, as also is tepid or spirit sponging. In cases in which the temperature is even then resistant, the cold pack should be used and repeated if necessary. Febrifuge drugs are to be avoided in such cases. Stimulants are now advisable to counteract circulatory failure.

(*b*) *Pulmonary cases.*—Linseed and mustard poultices are of service here, or kaolin poultice, applying these to the most "congested" parts. Volatile stimulants, sedative expectorants and diaphoretics are the most useful drugs: sp. ætheris co., the iodides in small amounts, bromide and chloride of ammonium, tinct. senegæ, tinct. belladonnæ and liq. ammon. acetatis. Ammon. carb. should only be used where sputa are present, and large doses are of doubtful value at any time. Oxygen delivered through a nasal catheter is useful in all severe cases with cyanosis.

(*c*) *Heart failure*, to be estimated more by the general state of the patient (facies, cyanosis, dyspnœa, delirium, posture) than by pulse-frequency or physical signs, is met by alcohol, strychnine injections, nikethamide (coramine) subcutaneously, and, as a measure supplementary to these, strophanthin $\frac{1}{500}$ grain in 20 minims of sterile saline solution, injected slowly into a vein of the arm and repeated, if indications are still present, in 8 or 12 hours.

(*d*) The *post-febrile stage*, often a stage of cardiac and nervous exhaustion in severe cases, requires some caution. Strict recumbency should be enjoined, with careful feeding, stimulants and tonics.

FOOT-AND-MOUTH DISEASE

Synonyms.—Aphtha Epizootica ; Epidemic Stomatitis.

Definition.—A contagious disease, due to a virus, communicated from animals to man, characterised by mild pyrexia, swelling and vesiculation of the tonue and buccal mucosa, accompanied, sometimes, by a vesicular eruption on the hands and fingers.

Ætiology.—Man is relatively insusceptible to infection which, however, is of almost world-wide distribution amongst cattle, pigs and sheep. Up to 1872 there were but few reported cases of supposed foot-and-mouth disease in man. In that year a more virulent form appeared in cattle, and human cases were more frequently described. Bussenius and Siegel in 1897 analysed the reports of more than 1500 cases ; the majority are sporadic or occur in small groups.

Three types of virus have been recognised by immunological tests: antiserum of types O and A (Vallée and Carré) and C (Waldman) has no protective influence against infection by either of the other two types. In cattle the virus enters through the mucosa of the alimentary tract, a septicæmia ensues during which all the secretions and excretions of the body become infective, with subsequent localisation in the specific lesions. The virus can remain active on hair or in soil for a month.

Foot-and-mouth disease is communicated to man: (1) By the consumption of unboiled milk from a cow suffering from the disease. (2) By direct inoculation: from (*a*) the saliva if infected animals, or (*b*) milking cows suffering from the specific eruption on the teats or udders. Those affected are for the most part either children, milkers, or cowmen.

Symptoms and Course.—The incubation period of foot-and-mouth disease in man appears to be the same as in cattle, namely, 2 to 5 days. Whatever the route of infection the disease sets in with slight headache, a mild grade pyrexia and dryness of the mouth. This state continues for a few days, and is then succeeded by a period of salivation and the development of the characteristic lesions—vesicles upon the lips and tongue, which contain yellowish-white turbid fluid. In 48 hours or so the vesicles rupture with the formation of superficial ulcers having a smooth purplish base. There may be considerable swelling of the tongue and mouth, which, with the pain, renders mastication and swallowing difficult. At the same time a crop of small vesicles may appear around the nails and on the hands ; they increase rapidly in size, become pustules and then scabs, which fall off early in the second week. In adults the disease runs a mild course with recovery in from 7 to 10 days. In young children, fed on infected unboiled milk, the condition is prone to be more severe because of the liability to anorexia, gastro-enteritis and diarrhœa.

Treatment.—This is entirely dietetic and symptomatic. A weak solution of permanganate of potash is perhaps the best local application ; strong antiseptics, whether to the mouth or to the hands, must not be employed.

HORDER.
A. E. GOW.

PSITTACOSIS

Definition.—An acute infective disease derived from parrots, resembling typhoid fever in its mode of onset and general features, but presenting also signs of an atypical pneumonia.

Ætiology.—The disease is derived from parrots (hence its name), the green Amazonian parrot being usually the source. Grey parrots, however, are not exempt, and love-birds also suffer from it. Infection is usually conveyed direct from a sick parrot to a human being who has been in close contact with the bird, but a parrot dead of the disease is also infectious. It is probable that a healthy parrot can act as a carrier. Infection from one human being to another, although it seems to occur occasionally, is very rare. In 1892, Nocard isolated a bacillus from the bone-marrow of an infected parrot, and named it the *Bacillus psittacosis*; it was afterwards shown, however, that this was identical with the *B. œrtrycke*. In none of the cases in recent outbreaks, however, has there been any evidence of the presence of this bacillus, and it is now proved by the work of Bedson that the infecting organism is a filtrable virus.

Pathology.—The post-mortem appearances are those of a severe septicæmia, with characteristic changes in the lungs. The latter do not present the picture of classical lobar pneumonia or broncho-pneumonia, but of a "peculiar hæmorrhagic vesicular pneumonia, complicated by pulmonary thrombosis and free from bacteria" (Turnbull). In addition, areas of mucopurulent bronchitis and broncho-pneumonia may occur from secondary infection. The gastro-intestinal tract is usually free from severe inflammation.

Symptoms.—The disease usually sets in rather suddenly after an incubation period of probably about 10 days. The rise of temperature is commonly abrupt, and headache is pronounced. Epistaxis sometimes occurs. The patient is generally dull and apathetic, and passes into a condition suggesting a typhoid infection. The abdomen may be slightly distended, and there may be a little sickness and diarrhœa at the outset. The spleen is not palpable, but in some cases a few rose-spots have been observed which are of a smaller size than the spots in typhoid fever. Pulmonary symptoms may be present from the outset, or appear after the disease has lasted some days. Cough is often frequent and troublesome, but, as a rule, there is little expectoration. Respiration may be rapid, but the pulse-rate remains low. The signs in the lung range from those of a bronchial catarrh up to massive, sometimes very dense, consolidation. Pleuritic signs are very rare. The disease usually lasts from 2 to 3 weeks, and the temperature may fall abruptly. Temporary rises of temperature during convalescence are often observed, and there may even be a complete relapse.

Diagnosis.—Clinically the disease can be suspected on circumstantial evidence. If one has a patient who presents a general resemblance to a case of typhoid or paratyphoid fever, but whose blood does not give the agglutination reactions, who presents also pulmonary symptoms and signs of an atypical sort, and who has also been brought into close contact with a sick parrot or love-bird, then the diagnosis is justified. A deceptive feature in the diagnosis from typhoid, however, is that sometimes the agglutination reaction to the *B. typhosus* is positive. Indeed, a positive agglutination to

one strain of typhoid organism occurring early in the disease and in a high degree of dilution is rather suggestive of psittacosis than otherwise. The blood cultures, however, are negative. It may be impossible at the outset to distinguish psittacosis from influenza, but the supervention of pulmonary complications *within the first few days* is in favour of the latter. Bacteriologically the existence of the disease is proved by the presence of a positive complement fixation reaction in the patient's serum.

Prognosis.—The mortality varies considerably in different epidemics, but may perhaps be put at about 1 in 6. Young people usually recover. Severe involvement of the lungs and failure to maintain a relatively slow pulse are unfavourable factors.

Treatment.—There is no specific treatment, and the use of convalescent serum has proved disappointing. Patients should be nursed with the usual precautions adopted in a typhoid case, but need not be further isolated. Special signs and symptoms must be treated as they arise.

PROPHYLAXIS consists in forbidding the importation of infected birds; cages should be kept clean, and the birds should not be fondled. A bird which falls sick should be immediately isolated or destroyed.

ROBERT HUTCHISON.

YELLOW FEVER

Synonyms.—Febris Flava; Typhus Icteroides; Yellow Jack; Black Vomit; Kendal's Fever; Fièvre Jaune; Fièbre Amarilla.

Definition.—An acute infectious disease of sudden onset, endemic in parts of tropical America and West Africa, characterised typically by pyrexia, vomiting, a slow pulse relative to the temperature, early albuminuria, and a tendency to hæmorrhages and jaundice. It is caused by a filtrable virus and, with the exception of jungle yellow fever, is transmitted to man by the common domestic mosquito, *Aëdes ægypti* (*Stegomyia fasciata*).

Ætiology.—The endemic haunts of yellow fever have been curtailed in recent years by the destruction of its intermediary host. A circle with its centre in the Isthmus of Panama, and embracing the northern parts of South America, the West Indian Islands and the southern parts of North America includes most of the area of its late prevalence in the Western Hemisphere. Recent work has shown unsuspected reservoirs of infection in the Amazon basin and in parts of Columbia, Venezuela and Brazil. The disease is widely endemic in West Africa, while cases occur far in the interior from the coast of Senegal eastward for over 3000 miles, and northward to the Sahara desert. Stokes, Noguchi and Young all died when investigating it there. Probably infection was acquired by direct contact with infective blood rather than by the mosquito vector, *Aëdes ægypti*, which Carroll in 1900 showed would transmit the disease after a period of 12 days, provided it was fed on the blood of a yellow-fever patient during the first 3 days of fever. Reed and Carroll also found that the injection of 0·1 c.c. of blood from a yellow-fever patient collected during the first 3 or 4 days of fever produced the disease, and that the serum after filtration remained infective. *Aëdes ægypti* bites in the day time, and is most aggressive in the early morning. Its domestic habits make it an efficient vector, as the larval stages develop

mainly in artificial containers in or near human habitations. Males and females are equally susceptible, and infection in childhood is common. This type of urban and rural yellow fever differs from jungle yellow fever, which is found in or near tropical forests in Brazil, where *Aëdes ægypti* is absent. Adult males who work in the jungle are mainly infected. Wild jungle mosquitoes have been found to harbour the virus, but the common vector is not yet known. Monkeys and probably other animals play an important rôle as reservoir hosts. In 1927 the West African Yellow Fever Commission found that the Rhesus monkey (*Macaca mulatta*) was susceptible, only 1 out of 30 monkeys surviving. One attack confers lifelong immunity and 0·1 c.c. of convalescent human serum protects monkeys. The virus, if dried, will keep for months; it penetrates the intact skin of both man and monkeys, but is no longer demonstrable in the blood and viscera after the fourth day.

The diameter of the virus as determined by filtration through collodion membranes lies between 17–28 millimicrons. It possesses two qualities, viscerotropism and neurotropism; when both are present it is known as "pantropic" virus. In 1930 Theiler found that if pantropic virus was inoculated intracerebrally into susceptible mice they developed encephalitis, unless immune serum was simultaneously injected. After repeated passage through the brain of mice the virus lost its viscerotropism or capacity to attack the abdominal and thoracic organs, and was converted into a neurotropic virus with fixed characters. Injection of this virus or of pantropic virus attenuated by tissue culture immunises against yellow fever and is the basis of prophylactic immunisation.

The fact that immune bodies are demonstrable in the blood of yellow fever cases shortly after infection, and persist permanently in recovered cases has been utilised to determine the endemic incidence of the disease. Mice are employed for the purpose. The protection test, as developed by Sawyer and Lloyd, consists of an intracerebral inoculation of starch solution, followed by the intraperitoneal injection of virus and the serum to be tested. In the absence of immune bodies in the serum the virus produces encephalitis and death within a fortnight; if immune bodies are present the animal remains unaffected. This test has been of great value in affording an index to past epidemics, and in accurately determining the past and present geographical distribution of the disease. Examination of liver specimens obtained by means of the viscerotome from persons dying of illness of not over 10 days' duration have also lead to the detection of unsuspected reservoirs of infection.

Pathology.—Death generally occurs between the fifth and ninth day of the disease. Rigor mortis comes on early. The skin may show ecchymoses and is an intense yellow colour, which becomes accentuated after death. The liver is of approximately normal size, reddish yellow, brownish yellow or "chamois leather" colour, and may show hæmorrhages. Microscopically a midzonal fatty degeneration is characteristic on the fourth or fifth day, but later all zones undergo necrosis, and the nuclei may contain acidophile inclusion bodies. The gall-bladder contains tenacious, dark bile. The kidneys are congested, and show cloudy swelling and fatty degeneration. Petechial hæmorrhages, casts and degeneration of the convoluted tubules are seen on section. The adrenals may show cortical fatty degeneration. The left ventricle is often dilated, and its muscle pale and flabby. Brady-

cardia is due to damage to the auriculo-ventricular bundle, and fatty degeneration of muscle cell-elements are common. Erosions and petechial hæmorrhage in the stomach and proximal duodenum occur, hence the coffee-ground vomit and the tarry blood in the entero-colon. The spleen is almost normal in size and appearance. The pleura and meninges may show hæmorrhages, the brain is congested, and the lungs congested and apt to show hæmorrhages.

Clinical pathology.—The outstanding pathological features are cloudy swelling and necrosis of the parenchymatous cells, especially of the liver and kidneys, and degeneration of the capillary endothelium, resulting in hæmorrhages. Jaundice and albuminuria with casts are thus produced. Hypoglycæmia related to liver inefficiency may occur from the fourth day onwards, while the van den Bergh may show a biphasic direct positive reaction and a positive indirect reaction of from 2 to 20 units. In the later stages the blood urea may be increased, and in monkeys Findlay found an increase in guanidine bodies. Though the leucocytes may vary from 5,000 to 15,000 per c.mm., leucopenia being the rule, the lowest counts occur about the fifth to sixth day; the neutrophiles are increased, the lymphocytes decreased and the eosinophiles tend to disappear. The clotting time is markedly increased. The cerebro-spinal fluid is under increased pressure and contains increased quantities of albumin and chlorides.

Symptoms.—The incubation period is from 3 to 5 days, but may be 10. Clinically, the disease is divided into: (1) Larval and mild forms; (2) Severe; (3) Malignant. In well-established severe cases the clinical features vary according as the liver, kidneys or heart bear the brunt of the attack, acute hepatitis and cholæmia, uræmia and anuria, and cardiac insufficiency being respectively manifest. Most cases show evidence of both renal and hepatic involvement.

1. *The larval and mild types.*—During epidemics, as well as where the disease is endemic, aberrant and irregular types are not infrequent; transient fever of 1 to 4 days duration, perhaps associated with albuminuria, occurs with rapid return to health. Where the pyrexia persists over 48 hours, headache, vomiting, eye pain and mild jaundice may ensue. Diagnosis in the larval forms is dependent on showing that convalescent serum is protective.

2. *Severe or ordinary types.*—The typical case presents three stages: (*a*) the sthenic; (*b*) the stage of remission on the third or fourth day; (*c*) the asthenic stage. In the *sthenic stage* the onset, which often occurs at night, is sudden with chilly sensations or a rigor, the temperature rapidly rising to 102° F. or 104° F. There is severe pain in the back and limbs, frontal headache with flushed face, injected conjunctivæ (ferrety eye) and photophobia. Prostration is severe, often disproportionally so to the temperature (Carter). The tongue is pointed and red; anorexia, nausea and vomiting, which may be bilious, appear. Epigastric discomfort and tenderness are characteristic, and insomnia is frequent. Albuminuria generally occurs on the second day and steadily increases. The pulse is at first rapid (90 to 110 per minute) and of high tension with raised blood pressure, but later slows until by the third day it may be 60 to 70 per minute despite the fact that the temperature remains elevated. This is known as Faget's sign, the pulse actually falling away from the temperature. It also remains slow when the temperature rises again in the relapse. Constipation is the rule.

Stage of remission.—About the third or fourth day the temperature may

fall to 100° F. or lower with amelioration of symptoms. Recovery may result or fever be re-established. Frequently this stage is absent altogether.

The asthenic stage.—The temperature rises again if it has remitted, turgidity of the face decreases, and jaundice now appears; it is first seen in the conjunctivæ and is not obvious in the skin until the fourth day of fever as a rule; sometimes, however, it is demonstrable on the third day. The gums are swollen and bleed on pressure, while the tongue is coated and later dry and brown. The liver is tender and only slightly, if at all, enlarged, while the spleen is not palpable. Hiccough may be very distressing, and black or "coffee ground" vomit, tarry stools and skin petechiæ may occur. Bradycardia is marked (40 to 60 per minute) and the blood pressure low. The urine is acid and decreased in quantity; it contains urobilin and much albumin, granular casts and possibly bile salts, bile pigments, bile-stained epithelial cells, and red blood corpuscles. Anuria is frequent in fatal cases. After the intermission the fever does not last as a rule more than 3 days.

Malignant forms.—In this type the temperature may reach 106° F. and profuse hæmorrhages, melæna, black vomit, epistaxis, hæmaturia, purpura, jaundice and anuria may develop by the third day. Symptoms referable to the nervous system such as hiccough, tremor, subsultus tendinum and delirium are also encountered, death from overwhelming toxæmia rapidly ensuing.

Complications.—Complications are uncommon, but boils, abscesses and troublesome jaundice, appearing for the first time in convalescence, may occur.

Course.—If the patient survives, the acute disease rarely lasts longer than 10 days, and convalescence generally progresses slowly but surely once a normal temperature is established. Relapses are rare and generally fatal.

Diagnosis.—Difficulties in diagnosis are mainly encountered in atypical cases, especially early in an epidemic. In the average case fever associated with undue prostration and early and increasing albuminuria should at once arouse suspicion, while later, the tender liver, absence of splenic enlargement, Faget's sign, hæmorrhages and jaundice appearing about the fourth day will be confirmatory. In blackwater fever, jaundice appears in the first 24 hours; in bilious remittent fever on or about the second day; while in Weil's disease it is generally found on the fourth or fifth day. Dengue, malignant tertian malaria, and relapsing fever also occasionally give rise to difficulty in diagnosis. Malaria, bilious remittent fever, and relapsing fever are generally associated with an enlarged spleen, while blood smears should reveal malaria parasites or spirochætes. Special laboratory investigations may be necessary to differentiate Weil's disease. In the larval forms of yellow fever intracerebral inoculation of susceptible mice with 0·03 c.c. of blood collected during the first 3 days of fever may reveal the virus. More frequently it will be necessary to take two specimens of blood at a fortnight's interval and establish a rise in the titre of protective antibody by the mouse protection test in order to establish the diagnosis.

Prognosis.—The prognosis differs in various epidemics, the mortality rate varying from 10–70 per cent., the average being 20–30 per cent. Anuria deep jaundice, black vomit, hæmorrhages and severe nervous disturbances are of grave significance.

Treatment.—PROPHYLACTIC.—The segregation of infected individuals in mosquito-protected wards, and the destruction of the adult and larval

stages of mosquitoes (Aëdes) have done much to stamp out the disease. Rubber gloves must be worn in collecting blood from all pyrexial cases in endemic areas. Convalescent serum affords temporary protection. All persons visiting or living in a yellow fever area should be vaccinated with virus modified by tissue culture. A single subcutaneous injection of 0·5–1·0 c.c. produces protective antibodies and confers an immunity which probably lasts several years. No local reaction follows inoculation, but fever with headache and general aching may develop on the sixth or seventh day.

CURATIVE.—Careful nursing of the patient in the recumbent position is essential, and as much fluid as can be taken is given during the acute illness, but food is contra-indicated. The juice of citrus fruits and dextrose and lactose are given in water; citrates should be added to the drinks to combat acidosis and alkalinize the urine. Only when the temperature has been normal after the second paroxysm can a gradual increase in food be permitted—rice water, chicken soup, Benger's, custard, etc.—and even in convalescence it is only gradually increased. In severe cases with vomiting 1 to 2 pints of 5 per cent. dextrose, given intravenously every 24 hours, may be helpful; also tap water may be administered by proctolysis. Calcium lactate, grs. 60 daily, is advocated to prevent hæmorrhage. Unfortunately, though protective to monkeys, convalescent serum does not affect the course of the disease once symptoms have appeared. Symptomatic treatment includes the use of an ice bag locally for headache, a mustard plaster to the epigastrium for hiccough, hot fomentations and catheterisation for retention and sedatives for insomnia. Champagne may help the vomiting. On admission a mild purgative is administered and constipation is subsequently treated by a daily enema. A cold sponge is indicated when the temperature exceeds 103° F.

PHLEBOTOMUS FEVER

Synonyms.—Papataci Fever; Three-day Fever; Sand-fly Fever; Simple Continued Fever; Pym's Fever.

Definition.—An acute specific fever lasting about 3 days due to a filtrable virus and spread by *Phlebotomus papatasii*.

Ætiology.—The disease occurs in parts of Africa, Asia, Northern Argentina and is common in the Mediterranean basin, in India, Mesopotamia, Persia, etc., where it affects especially white races, though natives also suffer. The virus is present in the peripheral blood for the first 24 hours, and sand-flies sucking up such blood become infective 7 or 8 days later and remain so for life. Experimentally, blood taken on the first and second days may produce the disease on inoculation, and volunteers bitten by infective flies develop fever in 2 to 7 days. One attack generally confers immunity.

Pathology.—This has been inadequately studied, as the disease is not fatal.

Symptoms.—Prodromata like malaise, vague pains, headache and weariness may usher in the disease, the onset of which is sudden, with chilly feelings or shivering, frontal headaches and lumbar pains. The temperature rises rapidly to 104° F. or 105° F. The face is flushed, the eyes injected, the throat and mouth congested, and the skin dry, though sometimes there

is sweating. Diarrhœa, joint pains and cramps may occur. Bradycardia is present, also a leucopenia of 4,000 to 5,000 leucocytes per c.mm. After 36 to 48 hours the temperature falls slowly to normal, accompanied perhaps by epistaxis or sweating. Convalescence is generally rapid, but depression and asthenia may persist for some days or even weeks. Afebrile and abortive forms are described.

Diagnosis.—The diagnosis lies between influenza, malaria and especially dengue, which it closely resembles, but secondary rises in temperature, secondary rashes and glandular enlargement rarely occur.

Treatment.—Destruction of sand-flies, the employment of a fine mesh net, and spraying bedrooms with 1 per cent. formalin are helpful. Medically, cases are treated by rest in bed during the fever, with cold sponging and a mixture of aspirin, phenacetin and caffeine citrate.

DENGUE

Synonyms.—Dandy Fever; Break-Bone Fever.

Definition.—A specific fever, generally lasting 6 to 7 days, due to a filtrable virus transmitted by *Aëdes ægypti*. A saddle-back temperature chart, severe joint pains and backache, leucopenia and a skin eruption about the third to the fourth day are characteristic.

Ætiology.—The disease occurs universally throughout the tropics and sub-tropics, and is often epidemic. All ages and sexes are liable. The virus exists in the blood for the first 3 days of fever and for 18 hours previously, and is communicable to man by direct inoculation during this period or by mosquitoes after feeding. The mosquito takes 11 days before becoming infective, and remains so for life.

Pathology.—Nothing definite is known of this, as the disease is so rarely fatal.

Symptoms.—Prodromata include general malaise and pains in the limbs, but generally the onset is absolutely sudden, with a rapidly rising temperature of 102° F. to 105° F., headache and aching eyeballs more marked on movement. The skin, especially of the face, is congested and shows a general flushing—the so-called primary rash. Backache is very severe, and much pain occurs at the muscular insertion about the joints. Insomnia, initial depression, anorexia, vomiting and constipation are not infrequent. The pulse, at first rapid, now begins to slow, and after 3 to 4 days the temperature falls by crisis, diarrhœa, sweating and epistaxis often synchronising with it. Symptoms now improve, but after 12 hours to 3 days the temperature rises again, giving rise to the saddle-back chart. Pains and depression recur, and a measly, roseolar rash fading on pressure appears, best seen on the dorsal surface of the hands and feet and spreading to the forearms and legs. Desquamation with itching may follow. Glandular enlargements are described in some epidemics, and a leucopenia with lymphocytosis is characteristic. After 2 or 3 days' fever the temperature falls and convalescence begins. Some cases present a one-phase fever in which no secondary rise occurs, while others show a continuous fever of 6 to 7 days with a terminal rise.

Complications and Sequelæ.—One attack may confer immunity, but

two and even three have been recorded. General debility combined with insomnia and mental depression may persist well into convalescence, and intractable muscular pains may lead to considerable crippling.

Diagnosis.—Influenza, measles, German measles, scarlet fever, rheumatic fever, secondary syphilis and malaria may be confused with dengue. Yellow fever is readily distinguished by the marked albuminuria and jaundice.

Prognosis.—Different epidemics vary in virulence, but the death-rate is very small.

Treatment.—Destruction of the vector, *Aëdes ægypti*, will prevent the disease. The patient should be kept in bed for 10 days on a light fluid diet. Liniments, a mixture of aspirin, phenacetin, and caffeine citrate, and even morphine may be required to allay the pains in the joints. In convalescence gentle massage, tonic treatment and a change of air should be advised.

RIFT VALLEY FEVER

Synonym.—Enzootic Hepatitis.

Definition.—A specific fever due to a filtrable virus causing fatal epidemics amongst sheep and cattle in British East Africa, and producing in man a three-day fever.

Ætiology.—This disease was first described by Daubney, Hudson and Graham in Kenya Colony as an epidemic amongst lambs, sheep and cattle. Possibly it occurs in other parts of the tropics. Man may be infected directly from contact with animals or from virus in the laboratory. The blood is infective, the virus passing through Berkefeld N. V. and W. filters. Experimentally, rats and mice are susceptible and die of the disease. The transmitting agent may possibly be a mosquito.

Pathology.—Pathological changes include fatty infiltration and a focal or generalised necrosis of the parenchyma of the liver in experimentally infected animals. The intestines may show congestion, and hæmorrhages may occur in different organs.

Symptoms.—The incubation period is 3 to 6 days. A dengue-like fever lasting 1 to 3 days is produced in man, characterised clinically by fever, rigors, headache, muscular pains and possibly epistaxis. There is a primary polymorphonuclear leucocytosis followed by a leucopenia (Findlay), and protective and complement fixation antibodies appear in the blood of man after infection. Three cases of laboratory infection have recently occurred in England.

Diagnosis.—The presence of a transient fever in natives herding sheep and cattle, or in laboratory workers handling the virus, should arouse suspicion; mouse inoculation would confirm the diagnosis.

LYMPHOPATHIA VENEREUM

Synonyms.—Climatic Bubo; Tropical Bubo; Lymphogranuloma Inguinale; Poradenitis.

Definition.—A venereal disease due to a filterable virus characterised by a herpetiform chancre on the genitalia or peri-anal region, inflammation of the corresponding regional lymphatic glands, and fever. In males the inguino-cruro-iliac glands and in females the pararectal and pelvic glands are chiefly involved. Chronic ulceration and elephantiasis of the pudenda are not uncommon in females, and inflammatory stricture of the rectum may occur in both sexes.

Ætiology.—The disease has a world-wide distribution, but is especially common in China, Japan, Malaya, East and West Africa, and in North and South America. Though more common amongst coloured races, especially negroes, it is being recognised with increasing frequency in Europe. The disease occurs mainly in adults, is essentially venereal in origin, and is commonly acquired in the tropics and sub-tropics following coitus with native women. Sailors often acquire the disease in Eastern ports. The virus particle has a diameter of 0·125 to 0·175 μ, is filtrable, and was first successfully transmitted to monkeys by intracerebral inoculation of bubo pus by Hellerström and Wassén. Mice are similarly susceptible. In guinea-pigs large buboes may follow the subcutaneous injection of sterile bubo pus. Surgeons have developed axillary buboes from lesions on the fingers when operating on infected patients, and children have acquired infection from simple contact.

Pathology.—The extirpated glands show marked periadenitis, and form conglomerated masses. The cut section often presents a reddish or violet tinge. Foci of purulent softening may occur, and sometimes pus cavities, containing thick muco-pus of a grey to light green colour, are produced by their coalescence. Microscopical sections of the bubo reveals granulomatous tissue, epithelioid cells, fibroblasts, occasional giant cells, and polymorphonuclear leucocytes; epithelioid cells with palisade arrangement are very characteristic. Chromatin staining inclusion bodies, known as Gamna bodies, are found within lymphocytes and plasmocytes in the infected glands.

Symptoms.—In males, the primary lesion is as a rule overlooked. It occurs as a small herpetiform ulcer, generally situated in the coronal sulcus on the penis, and appears a few days to 3 weeks after coitus. Swelling of the median group of inguinal glands draining the ano-genital region follows in about 2 or 3 weeks, the limits being 1 to 6 weeks. Bilateral glandular involvement occurs in 35 per cent. of the cases. The onset is generally insidious, with slight stiffness or tenderness in the groin, and fever. Often pain is absent; rarely it may be severe. The skin is at first red, but as swelling of the glands with periadenitis and hard brawny infiltration proceeds, it changes to a bluish-violet tint. The conglomerated glands are hard to the touch, generally only slightly tender, and show no fluctuation unless suppuration is advanced. Fistulæ form in about half the cases. Though the iliac glands are frequently enlarged and palpable, they never present clinical evidence of suppuration. Healing with scarring may occur within 2 months or be delayed 1½ years. The general symptoms include fever, anorexia, weakness and loss of weight. Although the fever is usually remittent in type no characteristic temperature chart is present, and not infrequently the temperature becomes normal in 7 to 10 days, but sometimes it is prolonged and a typhoid-like state supervenes. Recurrent fever is occasionally associated with extension of the adenitis. Rheumatic and allergic skin manifestations are not

uncommon, and include painful red swollen joints, erythema nodosum, erythema multiforme, scarlatiniform and urticarial eruptions.

In females, primary lesions may occur on the genitalia or peri-anal region, and the para-rectal glands are commonly involved; these glands often suppurate and form fistulæ which may open into the vagina, the rectum, or the skin near the anus. The disease runs a chronic course; fibrous stricture of the urethra, vagina and rectum may develop, or elephantiasis of the vulva (esthiomène) follow lymphatic obstruction. Polypoid swellings may occur about the anus, while the lower portion of the rectum may ulcerate and become converted into a narrow indurated ulcerated tube, with widespread fistulæ below the stricture. According to Stannus this is generally situated some 3 to 8 cm. above the anus. Rectal stricture is more common in females —especially in prostitutes—and is associated with the passage of blood, mucus and pus from the bowel, and increasing constipation.

Diagnosis.—Climatic bubo has been called the sixth venereal disease, and the history and clinical features are most important in making a correct diagnosis. Where periadenitis and induration are extreme, actinomycosis may be simulated. Herpes genitalis, filarial adenitis, septic and tuberculous adenitis, venereal bubo the result of chancroid, gonorrhœa and syphilis, as well as other buboes, such as result from plague, rat-bite fever and tularæmia, may need differentiation. Histological section of material obtained at biopsy and Frei's intradermal test, using a 1 in 10 dilution of virus-containing pus sterilised at 60° C., may be of assistance; 0·1 c.c. of this antigen is injected intradermally, readings being made at the end of 48 hours. A positive reaction is characterised by the appearance of a reddish, infiltrated papule, measuring from 7·5 to 20 mm. in diameter. It is regarded as a manifestation of cutaneous allergy, and is said to be specific for climatic bubo. Animal inoculation and the mouse protection test may be resorted to in doubtful cases.

Lesions in the ano-genital region must be differentiated from filarial elephantiasis and ulcerative granuloma pudenda. Polypoid swellings should be distinguished from piles, simple polyposis and bilharzia polyps. Rectal stricture which is not due to surgical or other trauma or new growth is almost certainly caused by this virus; in the past it has generally been erroneously attributed to gonorrhœa, chancroid, syphilis, or tuberculosis.

Prognosis.—The disease runs a different course in different individuals. In males, unless the rectum be involved, the outlook is good though the disease may last many months. In females, with extensive ano-genital manifestations, such as fibrous strictures and multiple fistulæ, permanent invalidism may result.

Treatment.—The patient should be put to bed, have a nutritious high vitamin diet, and given a course of sulphapyridine (M. and B. 693). If the glands are small and have not suppurated they are best left alone, but after the acute stage has subsided they may be painted with linimentum iodi. If suppuration has taken place, aseptic aspiration may be undertaken. Excision at this stage may result in secondary infection, and should not be attempted. When operative intervention is practised in early cases, it should be remembered that too extensive removal of the groin glands may result in elephantiasi and the femoral chain must be left intact.

C. THE MYCOSES

Numerous fungi are pathogenic to man, and the lesions caused thereby are conveniently described as the mycoses.

Some of the diseases, for example the ringworms, are described in other sections. Six of them will be described here—actinomycosis, mycetoma, sporotrichosis, aspergillosis and blastomycosis, the lesions of which are of the nature of infective granulomata.

ACTINOMYCOSIS

Synonym.—Ray-fungus Disease.

Definition.—A local infection, tending to become general, due to the *Streptothrix actinomyces*, producing granulomatous lesions chiefly in the jaw, skin, lung and digestive tract.

Ætiology.—*Actinomyces bovis* was first described by Böllinger in 1877 as the micro-organism producing large, hard, sarcomatous-like masses occurring about the jawbones of cattle, and in the following year Wolff and Israël found the same organism in human cases.

The characteristic of the disease is a suppurative lesion, the pus from which contains visible granules which, examined microscopically, are seen to have a centre of a closely meshed filamentous network, with a border of radially arranged striations, often ending in club-shaped bodies. Formerly these club-shaped bodies were thought to be spores, but they are now regarded as hyaline thickenings of the sheaths of the threads. The clubs are only found in preparations made from pus from active lesions, or in cultures on media in which serum or blood is employed.

It is essential in examining suspected pus to isolate a granule. If granules be not readily detected in the wound or in the pus, Colebrook has pointed out that if pus be vigorously shaken in a tube of water the granules, not being emulsified, will sink to the bottom and may be removed by a pipette. Microscopical examination is very much facilitated by crushing the granules between two slides. The mycelial filaments retain Gram's stain, while the clubs lose it and take the counter-stain. Culture is in any case difficult, depending to a large extent on the amount of secondary infection. To

eliminate this as far as possible the granules should be well shaken in a sterile saline solution, and then after crushing between sterile slides should be sown on to glucose agar plates which are incubated anaerobically, or crushed granules may be shaken up into melted glucose agar which is aspirated into long sterile tubes according to the method of Vignal. Numerous subcultures may be necessary to complete the isolation of the organism.

Mode of invasion.—Till recently the view has been held that actinomycosis was conveyed to cattle and man from vegetable sources. Colebrook, in a review of 28 cases coming under his observation, brings forward strong reasons for believing that the fungus may be present under normal conditions in the alimentary tract. He quotes Lord as finding similar organisms in carious teeth and tonsillar crypts, and himself found not dissimilar filamentous organisms in each of six carious teeth examined. He also has shown that the serum of heavily infected patients causes agglutination of suspensions of actinomyces, as also does the serum of inoculated rabbits. The same observer supports the observation of Klinger as to the frequent association with actinomyces bovis in actinomycotic lesions of a minute Gram-negative cocco-bacillus, to which Klinger gave the name of *Bacillus actinomycelium comitans*. The significance of the association is not known.

Symptoms.—These depend upon the anatomical distribution of the granulomata.

1. The Jaw and adjacent Structures.—When the infection occurs in these parts the patient presents a swelling very like a sarcoma, generally about the angle or ramus of the mandible. The swelling may, however, affect the submandibular tissues and lymph glands rather more than the jaw itself, and one of the writers has recently seen a case in which the lesion was confined to the glands. The swelling is tender, somewhat painful, and not generally so hard as in sarcoma. It may show one or more spots of softer consistency than the rest of the lump. In most cases there is no obvious source of infection inside the mouth; the assumption is—in the light of observations quoted above—that the avenue of invasion is a carious tooth, or the gums and periodontal membrane.

2. The Intestines; Appendicitis.—The favourite site of infection is the cæcum and appendix region. The disease manifests itself either as an attack of appendicitis, most often acute, in which case the diagnosis is made only at the time of laparotomy; or as a slowly growing lump in the right iliac fossa, with some pain, tenderness, and constitutional disturbance, in which case suspicion may be aroused as to its nature, if it be remembered that this region is a site of election for the ray fungus. There is a tendency for the infection to spread from the ileo-cæcal region—(*a*) to the adjacent *peritoneum*; (*b*) to the *abdominal wall*; (*c*) to the *liver*. For this reason it is rare to find the lesion confined to the appendix by the time operation takes place. For this reason, too, the first evidence of cæcal infection may be the involvement of the parietes in the lower right quadrant of the abdomen, in which case there is always a probability that the infection has spread from the bowel. The *liver* is sometimes involved alone, that is, without obvious intestinal infection. The disease is only to be distinguished from abscess by puncture or by free incision.

3. The Pleura and Lung.—Actinomycosis in these tissues is by no means rare (see section on Respiratory System, pp. 1216, 1269), and the

disease should constantly be borne in mind by the practitioner when faced with an obscure case in which indefinite physical signs appear at one base, with cough, fever and (not seldom) hæmoptysis. In some cases a fairly frank pleuritic effusion appears, and the bacteriological examination of the exudate reveals the nature of the disease. In other cases the clinical picture resembles a basal tuberculosis. As the disease progresses the differential diagnosis lies between ray fungus, bronchiectasis and new growth. Hæmoptysis which recurs in the absence of any evidence of tuberculosis in an obscure case of pulmonary disease, is highly suggestive of actinomycosis of the lung. The later stages of the disease still resemble pulmonary tuberculosis; wasting, intermittent fever, purulent expectoration, cough and physical signs of progressive lung infiltration with destruction.

4. The Skin.—Granulomata sometimes appear in the skin and subcutaneous tissues (*a*) alone, or (*b*) complicating the disease in deeper structures.

(*a*) The neck and scalp are the parts most often affected. The initial lesion is a rounded swelling, not very acute, and therefore resembling a tuberculoma rather than the result of a pyogenic infection, but usually firmer in texture and larger than the lesion seen in tuberculosis of the skin. It has therefore to be distinguished from sarcoma and from gumma. As the lesion progresses it involves the subcutaneous tissue and tends to ulcerate, after the appearance of one or more soft and dusky-red areas on it. When ulceration occurs at these points, pus escapes, and this contains the tell-tale granules characteristic of the infection. At this stage the appearance is not unlike that of a chronic carbuncle or a suppurating gumma. Ultimately the skin "breaks down" over a considerable area of the swelling, and a chronic ulcer forms, which discharges freely.

(*b*) Similar skin lesions appear not seldom in association with primary infections of deeper structures, these superficial deposits having the significance of metastatic pyæmic deposits.

5. The Brain.—The brain, like the skin, may be infected by direct spread from an adjacent lesion, or it may suffer by way of a general pyæmic process. In a case under the observation of C. Ernest West and Horder a chronic otitis media was complicated by granulomata in the scalp, from which the streptothrix was demonstrated in films and grown in tubes of blood-broth. Cerebral symptoms developed, and the patient died comatose. At the post-mortem examination a large abscess was found in the centrum ovale of one hemisphere, and the mycelial threads were found in the pus in considerable numbers.

Diagnosis.—Hints have been given in the preceding account relative to the differential diagnosis from tuberculoma, sarcoma, pyogenic infection and gumma. *The chief reason why actinomycosis goes unrecognised is that the possibility of its existence is overlooked.* All materials from a suspected case (pus, pleural exudate, sputa, material from liver puncture, excised lymph glands, etc.) should be carefully examined for mycelium, and the bacteriologist should have his attention drawn to the possibility of its presence. Sputa from a case of recurring hæmoptysis, in which a negative report in respect of tubercle bacilli has been returned on several occasions, have been found to contain threads of actinomyces when the necessary investigation has been specially asked for.

Course and Prognosis.—Although these vary much, there is, as may

be inferred from remarks already made, a tendency for ray-fungus infection to become pyæmic in character. It is this feature which gives the serious note to prognosis in all cases. In lesions about the jaw and in skin infections, that are primary and not associated with visceral infection, the outlook is not nearly so bad as when the lungs, liver or intestinal tract are involved and when the skin lesions are multiple and secondary. Early diagnosis, if possible before secondary infection (usually staphylococcus) has taken place, adds greatly to the chance of recovery. One of the most important points in connection with prognosis is the uncertainty as to the complete extirpation of the fungus after treatment has been apparently successful. Relapses are common, and must be allowed for in any thorough programme of treatment.

Treatment.—So soon as the diagnosis is made, the question should be raised whether or not radical surgical measures are practicable. If they are they should be pursued without delay; any abscess or infected area should be drained, or incised and freely curetted; infected lymph glands should be excised; doubtful teeth should be sacrificed. The exhibition of potassium iodide in full doses should follow these surgical measures, or should take their place in all cases in which they are for some reason impracticable. In some cases it is reasonable to try the patient's response to iodine before planning operative measures. The drug should be given freely diluted with water, and it should be gradually increased from an initial dose of 30 grains in the day to 60 grains, or even to 120 grains if this amount can be tolerated. If recovery takes place the iodine treatment should be renewed for certain periods now and again to guard against relapses.

Vaccine therapy is of help when combined with adequate surgical measures. The preparation of an autogenous vaccine presents few practical difficulties, and stock vaccines are available, containing 25 million mycelial fragments per cubic centimetre. If staphylococci be also present the appropriate vaccine may be combined with the mycelial one.

Treatment by X-rays has also been advocated as a supplementary measure.

SPOROTRICHOSIS

In this disease, which is much less common than actinomycosis, lesions (granulomata) appear in the skin, and rarely in the muscles and bones.

Ætiology.—The causative microbe was first described by Schenk in 1898. Two varieties, *Sporotrichum schenki* and *S. beurmanni*, were originally described, but are now generally regarded as identical. The organisms occur in pus as oval or fusiform spores, and grow in culture as a colourless branching septate mycelium, with clusters of brown fusiform spores on the ends of the filaments. Occasionally the spores are arranged round the filaments. They stain well with the aniline dyes, but irregularly with Gram's stain. Growth occurs under aerobic conditions only, and on ordinary laboratory media. Cultures are best made from closed lesions, which should be punctured with a wide-bore needle, and the material aspirated should be thickly sown on glucose agar plates, which should be kept at laboratory temperature. The colonies, which appear in from 4 to 10 days, are very

characteristic. At first white, thick and leathery, they later become convoluted and coffee-coloured, and still later may become black. Laboratory animals, especially mice and rats, are susceptible, the lesions resembling those in man; but the disease is seldom fatal. The serum of infected individuals agglutinates the spores of the organism, and specific immune bodies can be demonstrated by complement-fixation tests.

Symptoms and Diagnosis.—See p. 1467.

Treatment is on the same lines described for Actinomycosis.

ASPERGILLOSIS

Infections with aspergillus, usually *A. fumigatus*, have been observed in the middle ear, on abraded corneæ and in the lung. The organism is of the group of Ascomycetes; it grows on ordinary laboratory media, and frequently occurs as a contamination.

Cases of lung infection are not very rare (see p. 1217). They resemble cases of chronic pulmonary tuberculosis very closely; indeed, they are generally mistaken for this disease until investigation of the sputa reveals their true character.

HORDER.
A. E. GOW.
JOHN MATTHEWS.

MYCETOMA

Synonyms.—Madura Foot; Fungus Foot; Pseudo-actinomycosis.

Definition.—A chronic granulomatous condition affecting especially the feet, characterised by marked swelling and the appearance of external nodules connected with deeper sinuses which exude oily, purulent fluid containing various coloured fungoid granules.

Ætiology.—The disease is endemic in certain parts of India, especially in the Madras Presidency (Madura), but it also occurs in Ceylon, Madagascar, parts of Northern Africa such as Egypt, the Sudan and Algiers, as well as in Cochin-China, Senegambia, the United States, West Indies, and South America. It is found in country districts, and generally attacks those who go barefooted, the mycetoma fungus probably gaining access through thorn punctures, small cuts or abrasions. Males are more commonly affected than females, and the disease is especially prevalent in the third and fourth decades of life, being generally confined to natives. Many different fungi which have the capacity in animal tissues to produce grains composed of hyphæ have been described as causing mycetoma. Laveran divides them into two groups: (1) the Actinomycoses, caused by fungi of the genus Actinomyces (Discomyces, Nocardia, etc.); (2) the Maduramycoses, caused by true fungi, the most important of which is the genus Madurella. White, red and black varieties of mycetoma occur clinically.

Pathology.—On section through the softened, jelly-like tissue, sinuses and cystic dilatations communicate with external nodules and internal granulomatous infiltrations which ultimately implicate muscle, fascia and

bones, forming a honeycombed cheesy mass. Both the cysts and sinuses are filled with whitish-yellow, red or black granules like fish's roe, which microscopically show narrow, nucleated threads and peripheral, club-like swellings. Section shows fungoid granules surrounded by mononuclear and leucocytic infiltrations and by fibrous-tissue cells.

Symptoms.—The incubation period is not definitely known, but in about 50 per cent. of cases there is a history of trauma ; many weeks or months may elapse before local lesions develop. The first signs are the presence of one or more hard, painless, subcutaneous nodules which are about 0·5 to 1·0 cm. in diameter and generally involve the sole of the foot, and more rarely the hands, face and limbs. Unlike actinomycosis the glands and viscera are never affected, adenitis, if present, being due to secondary bacterial infection. After several months swelling increases, the nodules break down and ulcerate, sinuses are formed and discharge their characteristic contents. Finally, the parts become riddled with sinuses, exuding foul-smelling, semi-purulent fluid. The foot becomes more and more swollen and distorted, but it shows little tendency to pain or hæmorrhage. In the early stages the general health is not adversely affected, but later anæmia and cachexia develop if secondary bacterial infection supervenes.

Diagnosis.—This is readily made by finding the characteristic fungi in the pus, but the identification of the actual species of mycetoma requires detailed laboratory investigation.

Prognosis.—There is no tendency to natural cure, and if untreated the prognosis is bad, the patient generally dying from intercurrent disease or secondary infection within fifteen years of onset.

Treatment.—PROPHYLACTIC.—Protection of exposed parts, like the feet, from thorns and spikes of barley would probably prevent the disease, and walking barefooted is to be avoided.

CURATIVE.—Surgery is the only satisfactory treatment. In the early stages curettage, or local excision of the nodules with the electric cautery may prove successful. In sinus-riddled feet amputation is the only cure. Potassium iodide in large doses is worth a trial.

BLASTOMYCOSIS

Synonyms.—Gilchrist's Disease ; Chicago Disease.

Definition.—A term applied to certain chronic granulomatous lesions of the skin or viscera, caused by yeast-like blastomyces.

Ætiology.—People of any age are susceptible, but males in the industrial classes are most often affected. The disease was especially prevalent in Chicago, but is now known to occur in all parts of the world. Castellani holds that there are at least three different species of Blastomycoides—*B. immitis*, *B. dermatitidis* and *B. tularensis*.

Pathology.—Nodules, gummata, papillomata and ulcerations may be produced in the skin, and tumour-like granulomata and abscesses in the viscera. The pathological lesions resemble the tissue reactions induced by the tubercle bacillus, but the central necrosis is less, and yeast-like organisms are present.

Symptoms.—The clinical manifestations are very variable. Jacobson

divides the primary cutaneous manifestations into papulo-ulcerative, papillomatous and gummatous types: cutaneous lesions secondary to systemic blastomycosis consist of superficial ulcers with granulating bases which exude pus or form crusts. Local pain and discomfort are produced.

In systemic blastomycosis the clinical picture resembles a subacute or chronic pyæmia, and almost any organ may be involved; the lung (95 per cent.) and kidneys (30 per cent.) are most frequently implicated, producing localising features resembling pleurisy or pneumonia on the one hand and nephritis on the other. Osseous involvement and blastomycotic meningitis may also occur.

Diagnosis.—This depends on the demonstration of blastomyces in pus, sputum or cerebro-spinal fluid; moist specimens are prepared by mixing with a drop of sodium hydroxide (10 to 30 per cent.) and examined microscopically, when the round or oval, highly refractile bodies (5 to 20 μ) surrounded by a hyaline capsule, may be observed. They may also be cultured on glucose agar.

Prognosis.—Cases with localised cutaneous lesions as a rule ultimately recover if properly treated, but in systemic blastomycosis 90 per cent. of cases end fatally in a few weeks to 3 years (Jacobson). Cerebro-spinal cases invariably die.

Treatment.—Skin lesions should be radically treated by complete resection with the cautery, or curetted and cauterised. Radium and X-ray treatment combined with full doses of iodide, *i.e.* 20 to 60 grains three times a day, are sometimes successful. Systemic blastomycosis cases should receive large amounts of iodide, and autogenous vaccines are worth a trial.

COCCIDIOIDOSIS

Synonyms.—California Disease; Coccidioidal Granuloma.

Definition.—An acute, sub-acute or chronic disease, characterised by granuloma formation in the skin or viscera, caused by the hypho-mycetic fungus, *Coccidioides immitis*.

Ætiology.—The disease is endemic in certain parts of North America and affects persons of any age. Males of the working class are particularly prone. The causative agent is *C. immitis* which appears in the tissues or pus as a spherical, double-contoured body measuring 5 to 60 μ. The fungus is readily cultured and laboratory animals are susceptible.

Pathology.—The lesions are those of an infectious granuloma and the tissue changes include tubercles, caseation, necrosis, abscess formation, cavitation, fibrosis and even calcification.

Symptoms.—As in blastomycosis both cutaneous and systemic manifestations may be present, but the latter are more frequently observed. Acute, sub-acute and chronic types are described. Nodular lesions may involve the dermis, and flaccid tumours, gummatous-like ulcers, and abscesses containing thick mucoid pus may be found in the subcutaneous tissues. A scrofulodermic type of lesion involving the superficial lymph glands, especially of the neck, is also described. Systemic coccidioidosis frequently involves the lungs, when it resembles tuberculosis, though early hæmoptysis is rare. Meningitis and involvement of the bones of the foot, ribs and vertebral column may occur.

The disease is progressive in character, lasting a few weeks to several years.

Diagnosis.—Numerous diseases including tuberculosis, syphilis, blastomycosis, sporotrichosis, mycetoma and bacterial osteomyelitis may be simulated. Diagnosis essentially depends on isolating *C. immitis* from pathological exudates. X-rays may be of assistance where bone is implicated.

Prognosis.—The more chronic type of the disease responds if treated early, but once the viscera are involved recovery is doubtful. Acute cases die.

Treatment.—X-rays and iodides have proved disappointing. Jacobson recommends intramuscular injections of colloidal copper every 4 to 7 days, and coccidioidin (exotoxin and endotoxin) every 8 to 14 days, the interval being determined by the local and constitutional reaction. Carbon dioxide snow may be used for isolated local lesions. Where the lesions have been confined to one limb early amputation has resulted in cure.

TORULOSIS

Definition.—An infection produced by a yeast-like organism, *Torula histolytica*, possessing a special affinity for the cerebro-spinal system and lungs.

Ætiology.—The disease affects both men and women and has a widespread geographical distribution. Species of the genus Torula reproduce only by budding without mycelial or endospore formation and do not ferment sugar; in pus and cerebro-spinal fluid they appear as ovoid or spherical structures, measuring 3 to 15 μ, with definite cell walls (Jacobson).

Pathology.—Chronic leptomeningitis is present, while the brain shows tubercles and gelatinous cyst-like structures in which torulæ abound. Clear spaces containing gelatinous material are found round the parasites in the tissues, and this constant finding led Stoddard and Cutler to name the parasites *Torula histolytica*. Similar lesions may occur in the lung which may be honeycombed, the interstices being filled with gelatinous material.

Symptoms.—Occasionally localised torulosis involves the skin or mucous membranes, but much more commonly there is primary involvement of the cerebro-spinal system. The lungs are generally secondarily implicated, but we have observed one case in which the patient was treated for pulmonary tuberculosis many months before meningitis ensued; at autopsy the lungs showed extensive gelatinous infiltration.

Diagnosis.—Clinically, these cases simulate tuberculous meningitis, and unless cultures are made the torulæ may readily be mistaken for lymphocytes. The cerebro-spinal fluid is under increased pressure, and contains excess of globulin and lymphocytes, but the sugar reaction is negative.

Prognosis.—The course of the disease is sub-acute or chronic, lasting a few weeks to 2 years, with an average duration of 4½ months. In localised infections the outlook is fairly good, but systemic torulosis is practically always fatal.

Treatment.—Surgical resection with the cautery is the treatment for local lesions but no therapy is effective in generalised infections.

RHINOSPORIDIOSIS

Definition.—A chronic disease due to *Rhinosporidium seeberi* (Wernicke, 1903), which produces nasal polypi and papillomata of the cheek, conjunctiva and lachrymal sac.

Ætiology.—Until recently the organism was regarded as a protozoon, but Ashworth has now shown it to be a vegetable mould belonging to the order Phytomycetes. The younger forms are rounded bodies, some 6 microns in diameter, possessing a capsule, a single nucleus and cytoplasm containing food granules. Multiplication by fission occurs and sporangia or large cysts, 250–300 microns in diameter, with a cellulose coating result; later, numerous daughter cysts are discharged from a definite pore in the wall of the mother cyst. Infections have been recorded from India, Cochin-China, Ceylon, Argentine and North America. The mode of transmission is unknown, but a similar if not identical fungus, *Rhinosporidium equi*, affects the horse, and man may acquire the disease from this source.

Pathology.—The organisms develop in connective tissue cells, causing fibroblastic activity, round-cell infiltration and epithelial proliferation. Polypi result which may involve the nose, conjunctiva, lachrymal sac and ear, and papillomata of the penis and vulva have also been described.

Symptoms.—A history of nasal symptoms extending over years may be obtained. The polyps are soft, vascular, bleed easily and show a marked tendency to recur.

Treatment.—The polyps are removed surgically, a wire snare often being employed. Wright has observed tumours disappear after a course of tartar emetic intravenously.

D. SPIROCHÆTAL INFECTIONS

SYPHILIS

A specific disease due to entry of a micro-organism (*Spirochæta pallida* or *Treponema pallidum*) into the tissues, either by inoculation into the skin, mucous membrane, or veins (acquired syphilis), or by transmission *in utero* (congenital syphilis).

In acquired syphilis, unless conveyed by transfusion, a primary sore commonly develops at each site of inoculation, and may be followed after a few weeks by a succession of lesions of the skin, mucous membranes, subcutaneous tissues, arteries, muscles, bones, viscera and central nervous system, which may recur again and again at varying intervals throughout the patient's life. After many years, degeneration of the parenchyma of the brain (general paresis) or of the spinal cord (tabes dorsalis) may develop. From an early stage changes in the blood serum can be detected by the Wassermann and various flocculation tests. Any or all manifestations, even the primary, may

be omitted. In congenital syphilis and in syphilis acquired by transfusion the systemic disease is the first manifestation.

Ætiology.—The specific micro-organism was discovered by Schaudinn in 1905 and named by him *Treponema pallidum*. Subsequently this was changed to *Spirochæta pallida*, but the original name is preferred by many workers. *S. pallida* is a minute organism which in fresh specimens under dark-ground illumination appears as a bluish white, very delicate corkscrew. Its length varies from 5 to 24 μ (average 8 to 10 μ); the distance between individual coils is 1 μ, and the depth of each coil is 1 μ. It is very active in its own ground but slow in moving from place to place. It alternately contracts and expands its coils, bends into loops or forms itself into a right angle. It has been demonstrated in every syphilitic lesion, including the brains of general paralytics. It has a life of only a few hours under natural conditions outside the body, and is killed at once by drying, by comparatively low degrees of heat, and by much feebler antiseptics than suffice to destroy ordinary pathogenic organisms.

The usual methods of transmission are by sexual intercourse and to the fœtus *in utero*. It does not seem necessary for a person transmitting the disease by intercourse to be suffering at the time from syphilitic lesions of the external genitals, and it is clear that often the semen contains the micro-organism. The period during which a person suffering from syphilis is liable to convey the disease by sexual intercourse varies; after the second year the chances diminish, and it is unusual for infection to be passed on in this manner after the fifth year. There is no doubt, however, that in the case of the fœtus, although the mother is most dangerous in the first five years of her infection, this may be transmitted up to a much later period, and there is, in fact, no limit to the length of time during which an infected mother may transmit the disease to her unborn child; infection occurs most often in the second half of pregnancy. Accidental infection usually results from contamination of any minute abrasion with secretion from a syphilitic lesion. The most dangerous from this point of view are the primary sore and the early secondaries of acquired syphilis and the early lesions in congenital syphilis, but although it is possible to infect an animal with secretion from later or tertiary syphilides, the chances of conveying the disease at this period by ordinary social intercourse are extremely slight. Even in the earlier stages, owing to the low resistance of the organism to external agencies, the risks of accidental infection by ordinary social intercourse appear to be very slight, judging by the great prevalence of syphilis and yet the very low proportion of extragenital chancres in countries where the standards of personal hygiene are equal to those in Western Europe. A number of instances of infection by transfusion of blood have been recorded, and they include cases in which the donor was still in the incubation stage; on the other hand, tertiary syphilitics have now been used as donors in cases of emergency in a number of instances without harm to the recipients, and it is clear that the older the infection the less likely is the micro-organism to be in the blood stream.

Pathology.—Kolle and Evers have shown that, after inoculation by scarification, the micro-organism has reached the nearest lymph glands of a rabbit in half an hour, and those of a guinea-pig in 5 minutes. The syphilitic lesion of every stage is histologically the same—a granuloma composed of a

collection of epithelioid cells, plasma cells, very numerous lymphocytes and some giant cells, with obliterative endarteritis of the vessels.

The pathology of syphilitic arteritis is discussed on p. 1031. Here it may suffice to sketch the main general effects of syphilis on the vessels. The changes in the vessel wall may lead to aneurysmal dilatation, as in the case of the aorta and other large arteries of the body, and in the cerebral vessels. The aortic valve may be involved in syphilitic mesaortitis, with resulting regurgitation. A common result of syphilitic arteritis of smaller vessels is thrombosis of the vessel, with important effects resulting from failure of the blood to reach the part supplied. In tertiary lesions the cutting off of nutritional supplies to the centre and the action of the toxin lead to necrosis and liquefaction, as seen in the clear-cut ulceration which often characterises tertiary syphilitic granulomata. If bone is involved in the tertiary gumma it may necrose throughout as in the flat bones, or only partially as in the long bones. Where necrosis does not occur, the granulomatous tissue of a syphilitic lesion tends to become fibrous, though at the same time natural forces work towards its removal. If the exudate is comparatively small, as in some primary and in practically all secondary lesions, the exuded cells may all be removed. If the exudate is a large one, a considerable proportion of it may reach the fibrous stage before the natural scavengers have had time to remove it. Thus many primary lesions are marked by hard scars for years afterwards, and gummata, their centres having liquefied, may be enclosed by dense connective tissue. Bone gummata are often ringed by heaped-up bone of ivory hardness.

Scarring from formation of fibrous tissue and its subsequent contraction may have important effects on viscera, interfering seriously with their functions.

It is well known that syphilis is a milder disease in females than in males, and experimental evidence suggests that the difference is due to female sex hormones.

The changes which occur when the parenchyma of the central nervous system is invaded are described elsewhere.

Incubation and early course.—The incubation period varies from a minimum of about 10 days to a maximum of about 90, with an average of 3 to 4 weeks. A small papule then appears at each site of inoculation, and quickly enlarges to a round or oval sore about the size of a threepenny bit, a sixpence, or larger; the centre usually becomes eroded, or perhaps more deeply ulcerated, and the broken surface is surrounded by a dull-red areola varying in width from half to 2 or 3 mm. Beyond the confines of the eroded area the tissues are infiltrated, feeling tougher than the corresponding tissues on the other side of the part. This induration becomes more and more pronounced until in the case of some primary sores, it feels as if there were a button embedded in the tissues. The sore does not bleed easily when scraped, but serum oozes freely from it, and this serum usually teems with syphilitic organisms. The sore is comparatively painless.

Individual features vary with the site. Thus the most indurated are those on the under-surface and mouth of the prepuce in males, and the labia, posterior commissure and *portio uteri* in females. In the case of a sore at the reflection of the prepuce on to the *corona glandis*, when the prepuce is retracted, the lesion flicks over like a plate turning on its edge. A sore at the

mouth of the prepuce often converts it to a fibrous ring. Induration is easy to elicit in sores affecting one wall of the *fossa navicularis*, which then feels as if a plate were embedded in it. In primary sores of the glans itself induration is difficult to elicit owing to tightness of the tissues, but the sore is easy to recognise by its dull-red areola, even contour, eroded centre, and indolent progress; rarely a primary sore has been reported deep in the urethra, the diagnosis being made by urethroscopic examination together with the discovery of *S. pallida* in the scanty urethral discharge. Primary sores of the skin are dark red, covered with a dark scab, and tough in consistency. Ulceration is usually more marked in sores affecting the mouth and undersurface of the prepuce, the skin at the peno-scrotal angle, the tissues around the nails, the lips and the tonsils. Almost all primary sores are comparatively painless, but when affecting the terminal phalanx of a finger or thumb they may be exquisitely painful, and thus may be mistaken for whitlow. The primary sore affecting the prepuce, the skin of the penis, or (especially) the female labia may be accompanied by a toughly indurated œdema of the affected parts, which become somewhat livid; the same condition may affect the uterine cervix.

The course of the primary sore varies greatly. In some cases the lesion is fleeting and its apparent triviality may lead to neglect of treatment; the history of a substantial proportion of cases of tabes and general paresis is that the initial lesion was either unnoticed or was very trivial. The ordinary sore which remains untreated lasts for a month or longer, and long after the erosion has healed over, a button of indurated tissue may remain to mark the site; syphilitic organisms have been found by histological examination in such scars many years later; weeks or months after it has healed the sore may break down again. When a sore is infected by secondary organisms, ulceration is a more prominent feature, and in rare instances it becomes phagedenic. In such cases the surrounding tissues very rapidly become black and necrotic, and the resulting loss of tissue may involve large portions of the external genitals.

Shortly after the appearance of the primary sore the nearest lymph glands often become painlessly enlarged, and in the case of the penis the lymphatics running from the sore can frequently be felt below the skin. The affected glands may reach a large size, bulging out the overlying skin; and this, with the fact that there is no reddening of the skin or other sign of acute inflammation, often gives the clue to the nature of the sore on which it depends. In females if the inguinal glands escape, owing to the internal situation of the sore, enlarged pelvic glands may often be found by palpation through the vagina against the ischiac bone. Syphilitic buboes do not usually suppurate, but may do so if the sore has become contaminated by secondary organisms, so that suppuration should not weigh heavily against a diagnosis of syphilis. A week or so after the local lymph glands have begun to enlarge there is universal adenitis, which can be appreciated by palpation, particularly of the epitrochlear, axillary and cervical glands.

About this time, or when the sore is about 15 days old, the blood serum often for the first time gives positive Wassermann and other serum reactions, such as the Kahn, Kline, Meinicke, Müller, Sachs-Georgi and Sigma. The last six depend on directly visible changes which occur in mixtures of syphilitic serum and diluted extract of heart muscle prepared by special methods.

The percentage of cases in which the Wassermann and other reactions are given increases with the age of the disease until the outbreak of the skin lesions which manifest the next or secondary stage. Practically 100 per cent. of patients in the secondary stage are positive.

Diagnosis of the Primary Stage.—It is axiomatic that every genital sore and every non-malignant sore elsewhere on the body which is not easily accounted for should be examined for *S. pallida*. This should be done before any antiseptics have been applied, as they kill the organisms in the superficial layers and prejudice the success of the examination. The sore should first be cleaned with a swab and its edge scraped, or a fairly deep puncture made in its margin with the point of a scalpel or a vaccination lancet. The sore should then be squeezed and the serum collected after it has oozed for a few minutes. When the necessary apparatus is at hand it is better to examine the specimen at once by dark-ground illumination; if it has to be sent away, the serum should be allowed to run into a capillary tube, only one end of which need be sealed. Alternatively a good method is to puncture the nearest enlarged gland and aspirate a little of the gland juice. A moderately stout hollow needle is run obliquely into the gland, and a few minims of sterile saline injected into it. The gland is massaged and aspiration applied by a syringe.

Spiral organisms other than *S. pallida* may be seen in a specimen obtained from the genitals or the mouth. They are largely eliminated by taking care to clean the surface of the lesion before collecting the specimen. All coarsely spiral organisms should be excluded at once, and only three others need cause difficulty.

A fairly fine spirochæte, with closely set spirals, often found in specimens from the genitals is about twice as thick as *S. pallida*, shines more brightly, has a slight rusty tinge, and spirals which are not so cleanly cut as those of *S. pallida*. Two spirochætes may be found in the mouth, both as fine as, or finer than, *S. pallida*. One is distinguished by the angularity of its turns, the other by its spirals being much more closely set, so that it looks like a piece of twisted silk.

Clinically, primary syphilitic sores are distinguished from others by the incubation period, colour, indolence, surrounding infiltration, comparative painlessness, slighter tendency to bleed, indolent enlargement of neighbouring glands, and the presence of *S. pallida*. The length of the incubation period is a guide only when the patient has not been exposed to infection for over 10 days.

A collection of *herpetic vesicles* on the penis is made up of minute, pinhead sized circles without induration, but usually irritable.

Chancroid has an incubation period of only a few days; the sore is more inflammatory and undermined, often with a more irregular edge which is merely tipped with red and has no areola; it is excavated, rather than worn down. Chancroid may be accompanied by a bubo which tends to suppurate. A syphilitic bubo may, however, suppurate, so that it would be a mistake to exclude syphilis on the sole ground of suppuration. If the glands, though distinctly enlarged, showed no sign of active inflammation, it would be strong evidence in favour of syphilis. Since there may be a double infection, microscopical examination should be repeated at intervals until the sore has healed, and the serum be tested for 3 months.

Scabietic runs on the glans and skin of the penis are mound-like and not eroded or indurated.

Syphilitic sores in parts of the body other than the genitals are often overlooked, mainly because syphilis is not thought of in those parts. A unilateral tonsillitis should arouse suspicion, especially if associated with painless enlargement of the submaxillary glands on one side. Similarly, the clue to the nature of a lip chancre may be given by the glands. Primary sores affecting the terminal phalanx of a thumb or finger often simulate whitlows; the syphilitic sore is more brawny, and remains so much longer after the sore has been lanced.

Secondary Stage.—Usually, but by no means always, a generalised rash appears three to six weeks after the sore. It generally starts on the sides of the trunk as pinkish spots, varying in size from a split-pea to a little-finger-nail, which deepen in colour with age to a dull-red or somewhat brownish tint. At first they may be difficult to see, but become more manifest after the patient has been stripped for a few minutes. Sometimes the spots are slightly raised and urticarial in appearance (roseola urticata). The eruption spreads gradually over the trunk and limbs, and fades in a few weeks, leaving little or no staining. It may recur at a later period, and the spots are then annular or ring-like.

After the fading of the first roseola, a peculiar change in the distribution of the pigment may occur, especially on the necks of brunettes. The neck becomes generally discoloured, or looks dappled (syphilitic leucodermia), as if the pigment had been washed out of a number of circular areas, each about the size of the end of a finger-tip, and had collected at the margins. An unusually high proportion of cases of syphilitic leucodermia have been found to have syphilitic changes in the cerebro-spinal fluid.

The *papular* eruption follows closely after the roseolar, and takes a number of different forms, the commonest and usually the earliest being dome-shaped, dull-red papules distributed over the trunk, limbs and face. Most are about the size of a lentil, but amongst the smaller papules may be many larger ones, sometimes even the size of a silver threepence. The papule feels tough and when squeezed between finger and thumb appears glistening white, while its surface cracks slightly. Variations of the ordinary papular eruption are the papulo-squamous, squamous, papulo-pustular and pustular. In the *papulo-squamous* a large proportion of the papules are covered at their centres by loose scales. The *squamous* syphilide is a papular eruption in which scaling is a still more prominent feature. In the *papulo-pustular* syphilide the centre of the papule necroses, and looks rather like an acne spot. When the whole papule breaks down a pustular syphilide results and this may resemble a varicellar or a variolous eruption. A more severe and malignant form is the ecthymatous type, in which the papule breaks down quickly, and the underlying tissues are eroded or ulcerated. As the destruction of tissue extends, the secretion dries to a crust. This may become heaped up by the deposit of successive layers, and the result is a blackish crust, shaped like a limpet (*rupia*).

Peculiar appearance of the papular syphilide in different situations.—Between the buttocks, on the lateral surfaces of the scrotum, on the labia, and on the upper and inner sides of the thighs, the papular syphilide often becomes very prominent and wart-like, with a greyish-white appearance;

these syphilides are called *broad condylomata*; the whole of the contiguous surfaces of the buttocks may be covered with them. On the scrotum this syphilide often looks like white slightly raised rings with brownish centres; it is best displayed by stretching the skin. Between the toes, under the pendulant mammæ, and in almost all moist situations, papules tend to run together, and a moist, pinkish-red surface, fringed with loosened epithelium, is left. Condylomata and moist papules generally exude serum freely, and the discharge is rich in *S. pallida*. On the palms and soles the papules appear as flat or slightly raised spots, varying in size from a split-pea to a sixpence. They scale easily, leaving collars of loosened epithelium surrounding the shining papules; sometimes the lesions run together into large plaques traversed by weeping fissures. The finger-nails may show characteristic changes, more especially in the recurrent secondary stages. The end of the finger becomes pinkish-red and bulbous, and at the reflection of the skin on the nail are weeping granulations. The nail becomes brittle and lustreless and is shed. The papular syphilide may be well marked on the forehead, following the margin of the hair (*corona veneris*), and it is often possible to find many papules in the hairy scalp. On other parts of the face, especially about the naso-labial fold and the chin, the papules are often set in rings. In some cases the facial lesions may be prominent, especially at a naso-labial junction, appearing like condylomata; on account of its similarity to yaws this condition is called a framboesiform syphilide.

The small follicular syphilide usually appears later than the lenticulo-papular. It occurs in small clusters of minute brownish papules, often thickly distributed on the back. The affected areas, which may be as small as 1 cm. across, have a goose-skin appearance and the part generally looks as if it had not been properly washed. The *lichenoid* syphilide, also a late secondary manifestation, occurs as small flat red elevations a few millimetres across, often polyhedral.

Recurrent papular eruptions.—Recurrences of the papular eruption tend to be much more limited in distribution. A common form, the corymbose syphilide, appears as one or only a few rather densely packed groups of papules from 1 to 3 inches or more in diameter. In some cases in the centre of the group is a large papule and around it, separated by a zone of healthy skin, a crowd of smaller papules. The chief sites are the extensor surfaces of the arms, the shoulders, back and abdominal wall. Sometimes the recurrence is a single papule as big as a shilling; it may occur on the genital area and be mistaken for a primary sore.

The *hair* is shed to a varying degree in the secondary stage. In most cases the thinning is not particularly noticeable; in others the fall is patchy, giving the back of the head a moth-eaten appearance; and in a few the patient may become temporarily bald. The beard and eyebrows may participate in these changes.

The syphilitic eruption in the mouth and throat.—Before the rash appears on the body the soft palate may become erythematous. Other lesions of the mouth usually make their first appearance at the time of the papular syphilide of the skin. On the mucous surface of the lips and the pillars of the fauces the early syphilide is a greyish-white patch, edged with a pinkish-red areola, which marks it off from the surrounding mucous surface. On the pillars of the fauces the appearance is that of a snail-track creeping up over the pillar

on to the soft palate. On the tonsil the lesion tends to ulcerate rather deeply. The mucous patch on the lip is usually round or oval and, if it crosses the angle of the mouth, is fissured. On the sides of the tongue fissuring and ulceration are more pronounced, but on the under-surface there may be condylomata, while on the dorsum are pink, bald spots, the pile of the tongue having been rubbed off at each papule. The discharge from these lesions teems with syphilitic organisms, and is very contagious. Papules can also be seen in the nose, on the septum and the floor. In the larynx, by suitable examination, they can be seen chiefly on the epiglottis and aryepiglottidean folds; they are apt to become eroded and ulcerated, causing the husky voice often heard in syphilitic patients. As these lesions of the mouth and throat are more apt to recur in uncured cases than are those of the skin, it is very important to examine the mouth thoroughly in a possible case of syphilis.

Other mucous membranes.—Mucous patches also occur on other mucous membranes such as those of the labia, just within the vagina, at the posterior commissure, the cervix, just within the anal canal, and on the glans penis and the mucous surface of the prepuce. Usually these are eroded and appear as sharply defined lesions against the background of normal-looking mucous membrane. On the genitalia, especially on the glans, they are quite often diagnosed as primary lesions, but this error can usually be avoided if it is remembered that not all sores on the genitalia are primary chancres.

Joints and bursæ are not often affected in secondary syphilis, but occasionally an *acute synovitis* occurs. It is fairly painful, and usually worse at night. A more indolent form of synovitis causes swelling without pain or great limitation of movement. The tendon-sheaths may be affected similarly, and the tendency to formation of adhesions may lead to permanent limitation of movement. Mild *periostitis* and osteocopic pains, worse at night, may occur in the secondary stage or even before any rash appears, but bone affections are commoner in the tertiary.

Thrombo-phlebitis, in the form of painless nodules in the superficial veins, particularly in the legs and resembling erythema nodosum, sometimes occurs.

From about the sixth month, or even earlier, the patient may develop symptoms pointing to syphilitic disease of the *central nervous system*, which are dealt with elsewhere. It is well to remember that in over 30 per cent. of cases in the secondary stage changes in the cerebro-spinal fluid indicate invasion of the central nervous system, though only a small proportion of these cases show clinical signs of nervous disease; this fact should be borne in mind when eventually tests of cure are being considered.

Constitutional symptoms.—Fever.—Even in the incubation period rigor followed by some degree of fever and pains in the limbs may occur. In some cases, towards the end of the primary stage, or on the outbreak of the rash, the patient's temperature may become irregular, the pyrexia being intermittent, continuous, or remittent, and accompanied by some constitutional disturbance. In rare cases the fever and constitutional symptoms may be more prolonged and pronounced, and if no rash appears, the symptom-complex may be very puzzling. Its association with generalised adenopathy should arouse suspicion. Sometimes, just before the outbreak of the eruption, and during the early part of the secondary stage, the limbs ache and there may be definite lightning pains, which lends support to the idea that all these symptoms may possibly be due to meningeal involvement and irritation.

In the early secondary stage also, headache may be severe, and may not improbably be due also to meningeal involvement.

Anæmia.—The red cell count may be slightly reduced, to between 4,000,000 and 5,000,000, and the colour index be as low as 70 per cent. In the early stages the white cells may reach 20,000 per c.mm. In early untreated cases the increase is due to polynuclear leucocytes, but under treatment these give way to lymphocytes, which may constitute 65 per cent. of the total; this lymphocytosis may persist for months. In rare cases the anæmia may be much more severe, Müller having reported one with a blood state resembling that found in pernicious anæmia.

Diagnosis of Secondary Eruptions.—The maculo-roseolar syphilide is fairly easy to distinguish by the history of a primary sore with indolent adenitis; by the subcuticular, deeply grounded appearance of the spots, which first appear on the flanks, very rarely itch, and are pinkish or dull-red, and by the coincidence of positive serum reactions. Other erythemata are brighter red and irritable, and often affect the backs of the hands. *Seborrhœa* is more superficial and is more scaly, the scales being greasy. *Pityriasis rosea* is often mistaken for syphilis, but the lesions are brighter in colour and more irritable; they tend to become annular, with their centres covered by branny scales. *Ringworm* is more superficial and irritable, and the fungus can be found in scrapings from its border. *Tinea cruris* or *dhobie's itch* affects a triangle at the upper and inner part of the thigh; it is brighter red, more irritable, and quite superficial. *Drug rashes* are more inflammatory and irritable; they appear more suddenly, and are associated with a history of the patient having taken such a drug as copaiba, cubebs, antipyrine, quinine or belladonna. The *eruptions of specific fevers* are usually accompanied by more pronounced constitutional symptoms.

The ordinary dome-shaped papular syphilide is usually easy to distinguish from a non-syphilitic eruption. The indurated feel of the papule, its shining appearance when pinched, its readiness to scale, and its dull or pinkish-red colour are valuable diagnostic signs, as is also the association with mouth and throat lesions. The different appearances which a papular syphilide presents in different parts of the body, such as dry papules on the trunk and most areas of the limbs, moist papules on the scrotum, between the toes and in other moist, warm parts, and wart-like condylomata on the scrotum, contrast strongly with non-syphilitic dermatoses, which are true to type, wherever situated. *The microscopic test should always be applied to the exudate from the lesion in any doubtful case,* and very rarely fails, even with the papulo-pustular or the pustular syphilide. *Acne spots* are more inflammatory, and affect the upper front of the chest and between the shoulders behind, rather than the flanks, loins and limbs. Pus can usually be expressed from blind acne pimples when they are pricked and squeezed. *Molluscum* spots are white and umbilicated, while caseous matter can be squeezed from their centres. *Lichen ruber planus* is characterised by flatter, smaller, polygonal spots of a violet tinge and waxy covering; it is more irritable. *Psoriasis* is usually less indurated, more superficial, bleeds at a number of points when slightly scraped, and affects the extensor rather than the flexor surfaces of the limbs; the scales are more silvery, and in moist situations the rash remains true to type, contrasting with the syphilide, which here becomes sodden with the secretion that freely oozes from it. *Varicellar spots* are

vesicular at one stage, more superficial and irritable. In *variola*, besides the febrile prodrome with backache, the spots are of uniform character and appear first on face and wrists. *Bromide* and *iodide* eruptions appear more suddenly, and are considerably more irritable. The deeper forms of pustular syphilide with considerable crusting, such as the superficial and deep ecthymatous, or the rupial, are distinguished from ordinary *impetigo* by the darker colour of the crusts, the circular rather than linear shape of the lesions, and the greater degree of tissue destruction below the crusts. *Scabies* is often mistaken for a crusted syphilide, and vice versa. The individual scabietic lesion is easy to recognise, but the tendency is to forget that scabies and syphilis often coexist.

Secondary syphilitic mouth lesions are easily diagnosed by the characters mentioned. *Vincent's angina* may cause confusion, but there is no pinkish areola, and the microscope easily settles the diagnosis.

Tertiary Lesions.—There is no sharply dividing line between the secondary stage and the tertiary, since the earliest tertiary lesion, the tubero-serpiginous, is merely a collection of large papules, which are more deeply embedded, and tend more to ulceration than the papules of what is called the early secondary stage.

The *tubero-serpiginous syphilide* occurs in one or more isolated areas of the skin as a collection of skin gummata, each about the size of a pea, often running into one another to form a more or less continuous, brownish-red ridge, often arranged in roughly concentric circles, or arcs of circles, or as a snake-like line of varying length. The affected area may be as small as a finger-nail or larger than a hand. The individual gummata may degenerate only so slightly as to produce some scaling, or may ulcerate more deeply and become crusted. The lesion extends centrifugally, and leaves in its wake a reddish-stained area in which are supple, papery scars, showing well the concentric distribution of the lesion. Sometimes the nodules do not resolve as the lesion extends, and a red nodular plaque of indurated tissue is formed. On the palms the lesion may be serpiginous as described above, or affect chiefly the folds, which become fissured. In some ulcerative cases extension is more rapid than healing, and a large patch of small skin ulcers may be left in the wake of the advancing arcs of new lesions. Very rarely, and then mostly when situated close to the angles of the mouth, or at a nasal orifice, the ulcer may become phagedenic, causing extensive destruction of tissue. The areas chiefly affected are those exposed to injury or constant friction.

Gummata of the subcutaneous tissues and muscles grow up as indiarubbery lumps which vary in size from a shrapnel bullet to an orange, or larger. They are painless, quietly expanding growths, which tend to break down in the centre, leaving clean-cut ulcers with tough, wash-leather sloughs occupying the bases. Sometimes the affected muscles are diffusely infiltrated, and much deformity results when the degenerated tissue is replaced by scar.

The *joints, bursæ and tendon-sheaths* are not often invaded in tertiary syphilis. The parts affected are, again, those most exposed to stress and strain, such as the knee-joint and the prepatellar bursa. The swelling is non-inflammatory, of soft rubbery consistence, and follows the lines of the affected joint, bursa or tendon sheath.

The *bones* are affected in tertiary syphilis in different ways, and in each of them the affection is commonly accompanied by boring or gnawing pains

worse at night (osteocopic pains). In the long bones the most usual manifestation in acquired syphilis is a localised gumma which either ossifies and remains as a boss on the bone or breaks down in the centre, leaving either a depression ringed with ivory-hard bone, or an ulcer. If the process begins deeper, the local swelling may not be so obvious and, eventually, with discharge of the necrotic contents, one or two fistulous openings lead to the interior of the bone. Diffuse osteitis and periostitis are not so common in acquired as in congenital syphilis. A sign of congenital syphilis in adolescents and adults is the sabre-scabbard tibia resulting from diffuse periostitis in earlier years; the bone is thickened from before backwards, and its anterior crest is curved with its convexity forwards, giving the bone the shape from which the condition derives its name. Of the long bones, the most commonly affected in acquired syphilis are the clavicle (sterno-clavicular joint), sternum, ribs, tibia and femur; but no bone is immune, and the process is particularly apt to affect those which have received a blow or other injury. Syphilitic dactylitis is very uncommon. Usually the proximal phalanx is affected, and a quiet, painless swelling results. Sometimes a sinus forms and the bone becomes rarefied. The whole bone may become permanently thickened, or absorption may result in shortening. The cranial bones tend especially to become carious under gummatous infiltration, and some of the worst mutilations result from syphilitic caries of the bones of the nose and palate. After a period of ozœna the bridge of the nose may fall in, or a large perforation suddenly appear in the hard palate. The process may spread to the skin and most disfiguring ulceration of the face ensue. Gummata of the cranial vault may start in the inner or the outer tables of the affected bones. In the latter case, unless the resulting swelling is absorbed under treatment, a circular or perhaps a horse-shoe- or trefoil-shaped ulcer is formed with an ivory-hard ridge. The skull may be perforated, but usually by then the cranial cavity has been shut off. If the inner table is first affected, irritative and pressure symptoms result. Vertebral gummata are rare; according to their situation they may cause retro-pharyngeal, lumbar, or iliac abscesses. Rarely they may cause pressure on the cord.

The *mouth and throat* often suffer severely in tertiary syphilis. Gumma of the tonsil is followed by ulceration. The soft palate may be strewn with a number of pea-like nodules which often ulcerate and result in all grades of deformity. Perforation, usually at the junction with the hard palate, is common, and sometimes the soft palate becomes adherent to the posterior pharyngeal wall. Perforation of the hard palate may result from gummata commencing on the mouth side.

In the *tongue* discrete gummata may eventually reach the surface and cause deeply punched-out ulcers. In a form analogous to the tubero-serpiginous syphilide a number of pea-like nodules affect a moderately large area of the tongue. This becomes swollen and tender, but, unlike the diffuse glossitis mentioned below, is very amenable to treatment. A much commoner manifestation of tertiary syphilis of the tongue is diffuse glossitis, which may be deep or superficial. The affected portions are swollen and the surface is smooth, hard, inelastic and usually covered by a bluish-white pellicle (*leucoplakia*). On retrogression, the tongue becomes cut up into numerous islands by fissures of varying depth. The tongue is tender, and intolerant of spices and hot food.

The insides of the cheeks opposite the gap between the upper and lower teeth often show leucoplakia as a white ridge cut up herringbone fashion, which is quite characteristic.

Tertiary syphilis of the *testicle* occurs in two forms, diffuse interstitial and nodular. In the former the testicle slowly enlarges and becomes heavy but remains quite smooth ; the testicular sensation is lost. In the nodular form, often engrafted on the diffuse, gummata project like bosses from the surface of the testis. The epididymis is usually not palpable, and commonly the cord is moderately thickened. There may be a hydrocele. The gummata may break down, giving rise to a form of *fungus testis*. Syphilitic epididymitis is rare, and syphilitic prostatitis more so. It is interesting that, although histological evidence of involvement of the body of the testicle can be found in almost every case, changes in the ovaries are very rare.

Fever occurs in some cases, and its dependence on syphilis has been shown by its response to anti-syphilitic treatment. It has been seen mostly in hepatic syphilis. As examples of the type of fever and the importance of an investigation with syphilis in view in cases of obscure pyrexia, the disease has been mistaken for rheumatic fever in those cases of the former in which there was periostitis in the vicinity of joints ; it has also been mistaken for tuberculosis.

Diagnosis of Tertiary Lesions.—An indolent swelling, or an ulcer preceded by a swelling, the lesion being obviously deeply embedded in the tissues or breaking down in the middle (which contains a characteristically gummy material) and sclerosing at the margin, with a circular, crescentic or evenly sinuous contour, and brownish-red in colour, should always arouse a suspicion of syphilis. Denial of primary sore, or of secondary lesions, is of no importance, as they may never have appeared or have long ago been forgotten. The positive serum reactions may mislead, since by no means all ulcers in an old syphilitic are themselves syphilitic. On the other hand, negative serum reactions are rather strong evidence against tertiary syphilis. *Epithelioma* is perhaps more likely to be confused with tertiary syphilis when the lesion is in the mouth, but epithelioma has a considerably harder margin, and the edge is rolled, not clean-cut. A positive serum reaction may be a trap, as epithelioma is often engrafted on an old syphilitic glossitis. Ulcers on the legs resulting from *varicose veins* or *impetigo* may arouse a suspicion of syphilis. They are usually much less regular in contour and associated with more inflammatory or congestive manifestations. Syphilitic orchitis is easily distinguished from other conditions by the evenly smooth hardness of the testicle, the weight and the absence of testicular feeling. Syphilis of the viscera and of the central nervous system is dealt with in other sections of this work.

Congenital Syphilis

An infected mother can transmit syphilis to her offspring long after she has ceased to be sexually contagious. Syphilis transmitted to the fœtus during the early months or years of the mother's disease is usually fatal, and a miscarriage results. In the classical case, in successive pregnancies miscarriages of viable fœtus are succeeded by still-births at term, by infants born alive but dying shortly afterwards, by infants which survive though

syphilitic, and eventually by healthy ones. This history of gradual attenuation of the infection is, however, not invariable; in some families a healthy infant may be sandwiched between diseased ones, and in the case of twins one only may be syphilitic. It is generally believed that transmission almost always occurs through infection of the mother, though a few workers consider that the ovum can be infected directly. The fœtus is commonly infected in the second half of pregnancy.

Symptoms.—A syphilitic infant born alive may show an eruption of bullæ or pustules resting on dark-red bases. The secretion contains *S. pallida* in large numbers. A commoner event is the maculo-roseolar eruption, coming on about 3 weeks or a month after birth. It selects chiefly the napkin area, the neighbourhood of the nose and mouth, and the palms and soles, but the whole trunk and limbs may be affected. The macules often run together into large patches which may be annular, as in the recurrent form of acquired syphilis. In moist areas, and where the rash is exposed to friction, the affected area becomes red and glazed, or crusted. Condylomata and moist papules occur and ulcerative fissures or rhagades may form at the angles of the mouth. These often leave radiating scars which remain as stigmata of the disease. The nails may become opaque and irregular, or there is infiltration and oozing of serum around the nail, which is loosened and shed. The hair is often shed extensively; on the other hand, syphilitic infants may grow an abundant crop of hair, which has been called the "syphilitic mop," though it occurs in other diseases. Mucous patches in the nose, mouth, throat and larynx cause the well-known "snuffles" and the hoarse, raucous cry of the syphilitic infant. Suppurative otitis media is often an early manifestation, and leads to hopeless deafness.

Tertiary lesions may appear very early, or not until the ages of 7, 14, 21, or even later. Thus diffuse interstitial orchitis may occur during the first 6 months. Skin gummata may appear in the first year or two as small infiltrates which break in the centre to discharge their mucoid contents. Tertiary lesions of the mouth and throat may appear at any time after the first year, and result in perforation of the palate and great deformity of the soft palate and faucial pillars. Destruction of the nasal support results in saddle-nose, and from the age of about 11 there is a liability to sudden deafness from gummatous changes of the internal ear. The affection usually starts in one ear, but quickly follows in the other, and the child becomes permanently deaf. Choroiditis and iritis may appear as early as the age of 5 months, and, unless properly treated, lead to blindness, or considerable impairment of sight. Interstitial keratitis may begin at any age from 6 to 30 or even later. Usually it starts in one eye, and the other follows suit in a few months, often in spite of treatment. The cornea of the affected eye gradually becomes opaque from the margin inwards, and this is followed by vascularisation, causing a pink patch (*salmon patch*); the cornea may gradually weaken and bulge before the intra-ocular pressure, or it may ulcerate. Gradually, after many months, the cornea may clear more or less completely, but the patient is often left with permanently damaged sight owing to concomitant iritis and choroiditis. The permanent teeth may show signs of congenital syphilis in the form of notching of certain teeth, which are narrowed at their cutting bases (*Hutchinson's teeth*). The two upper central incisors are much the most usually affected, but all the incisors may be notched. These

characteristics are usually lost after the age of 20. The first molars are often dome-shaped (*Moon's teeth*).

The long bones may be affected in various ways. Syphilitic epiphysitis (Wegner's "osteo-chondritis syphilitica") is a very constant effect of congenital syphilis, being detectable at birth by radiographic examination, which shows broadening and irregularity of the epiphyseodiaphyseal zone. This radiographic examination is very valuable for diagnosis during the first 6 months; afterwards the appearances may not be so characteristic. Epiphysitis may cause signs simulating paralysis (*syphilitic pseudo-paralysis*) owing to the rapid loss of movement which occurs. Movement of the limb causes severe pain, which explains the apparent paralysis. The epiphysis is swollen, and occasionally definite separation occurs. Arthritis may be associated with epiphysitis, and the joint may suppurate. Between 5 and 18 years of age chronic synovitis may appear, affecting chiefly the knees, with swelling of joints (Clutton's joints), but with slight pain or intererence with movement.

Dactylitis occurring in the second year causes fusiform swelling of the proximal phalanges of two or more fingers, or, more rarely, toes. At a later period in childhood, between the ages of 8 and 14, chronic periostitis of long bones is apt to cause characteristic deformities, best shown in the tibiæ, which becomes shaped like sabre-scabbards.

The visceral and nervous affections of congenital syphilis are dealt with in other sections, and here it must suffice to say that in infants and young children anæmia and marasmus, as also delayed development and proneness to death from intercurrent affections, are common consequences of congenital syphilis.

Diagnosis.—The serum reactions at birth and for some weeks afterwards are of no help in deciding whether or not it has been infected. It has been shown by Fildes, Whitridge Williams, Cruickshank, Dunham and others that an important proportion of those born with positive blood become negative later, and vice versa. In a non-syphilitic infant any positive reaction dies out rather quickly, and if there is reason to hope that, through treatment of the mother or the age of the infection, the infant has escaped, before accepting a positive reaction as diagnostic the test should be repeated quantitatively at weekly intervals; maintenance or strengthening of the reaction over some weeks would justify a diagnosis, and vice versa.

Syphilitic pemphigus occurs on the palms, is earlier than ordinary *pemphigus neonatorum*, and *S. pallida* can be found in the secretion. Ordinary *erythemata* are brighter red, and associated with friction and moisture such as from wet napkins, while the syphilide is not necessarily accounted for by friction, or by moisture, and is associated with such signs as "snuffles" and chronic laryngitis.

Syphilitic epiphysitis is distinguished from *true paralysis* by the pain on movement and contraction of the muscles when the skin is irritated. It occurs earlier than *scurvy* or *rickets*, appearing about the third week, and is associated with the skin and mucous-membrane lesions of syphilis. It is well to remember that syphilis has been found to be responsible for many of the nutritional and mental disorders of childhood, and that it is advisable to investigate every obscure case with syphilis in view.

Treatment.—PROPHYLACTIC.—For males a good condom is a safeguard

so far as the parts which it covers are concerned; it also protects the female. It should be removed with care to prevent contamination of the parts by the discharge on it. Whether or not a condom is used it is advisable to disinfect, by washing well with soap and water and then steeping the parts for some minutes in $\frac{1}{2000}$ mercuric potassium iodide solution, or $\frac{1}{2000}$ mercury oxycyanide lotion. After this the parts should be anointed with an ointment, such as Gauducheau's, viz., mercury cyanide, 0·10; thymol, 1·75; calomel, 25·00; lanolin, 50·00; liquid paraffin, 10·00; soft paraffin to 100·00. Some mercury oxycyanide lotion $\frac{1}{4000}$ may be injected into the urethra after urination; in urination the meatus should be alternately squeezed and released so that the urine first distends and then rushes forcibly from the urethra. In females the prior insertion of a suppository which foams on insertion into the vagina is most likely to prevent contact of the secretion with the mucous membrane of the vagina and cervix; it should be followed by an antiseptic douche. Washing of the external genitals, followed by their inunction with ointment as above, should be practised as in males. It is important to remember that in all cases disinfection should be prompt and thorough.

Prophylaxis by ingestion or injection of anti-syphilitic remedies is not recommended, because it may only mask the symptoms for many months.

As any prophylactic measure may prevent only the appearance of the chancre, it should be followed by blood tests for at least 3 months.

Accidental infection of fingers, lips and other extra-genital parts is best prevented by avoiding contamination with fresh secretions from persons in the earlier stages. These should be warned of the risk arising from sharing table utensils, crockery, and house linen with others. They should not kiss others or talk directly into people's faces, and articles which they have used should be dipped in very hot water. A further precaution is to keep open lesions smeared with an antiseptic ointment such as the cream mentioned above.

The prevention of transmission to offspring is primarily a matter of preventing infection of mothers. A man who has contracted syphilis should be advised to wait for at least five years before marrying; by that time the risk of transmission by sexual intercourse has usually gone, whatever the treatment. The period can be shortened by treatment, but this must be prolonged and thorough. A syphilitic woman is liable to convey the disease to her offspring throughout the child-bearing period, especially in the first five years of the infection, but efficient treatment commenced in the first half of pregnancy will usually protect the fœtus; if treatment is started later and the mother's infection is recent, it is usually safest to regard it as remédial and to continue treating the infant after birth.

CURATIVE.—The remedies most commonly employed for the treatment of syphilis are preparations of arsenic, mercury, bismuth and iodine. The first three destroy the parasites; the last stimulate the removal of granulomatous tissue.

Arsenical preparations.—These are organic compounds in which the arsenic is trivalent or pentavalent.

Trivalent arsenical remedies.—These are by far the most efficient of the arsenical remedies for the treatment of syphilis outside the central nervous system and, beginning with the famous "606" or the Ehrlich-Hata remedy introduced to the public in 1910, have revolutionised the treatment of

syphilis. There are now a large number of these compounds whose different trade names are apt to be confusing, but fortunately they are subject to Regulations under the Therapeutic Substances Act, and each, besides being required to satisfy certain tests for toxicity and therapeutic potency, must bear on its label an official name according to its chemical constitution. The following are the principal remedies in this class.

(i) Arsphenamine, or the dihydrochloride of dioxy-diamino-arsenobenzene, which is the original "606," or salvarsan; it is sold under the trade names, Arsenobillon, Diarsenol, Kharsivan and Salvarsan; and it must have an arsenical content not less than 30 per cent. and not more than 34 per cent. (ii) The disodium salt of (i), or sodium salvarsan; it contains about 20 per cent. As. (iii) Neoarsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphoxylic acid, which is the original "914," or neosalvarsan; it is sold under the trade names, Neoarsphenamine-Evans, Neokharsivan, Neosalvarsan, Novarsan, Novarsenobillon and Novostab; it must contain not less than 18 per cent. and not more than 21 per cent. As. (iv) Sulpharsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphurous acid; it is sold under the trade names, Kharsulphan, Metarsenobillon, Myosalvarsan, Sulfarsenol and Sulphostab; and its arsenical content is the same as that of neoarsphenamine. (v) Arsphenamine glucoside, or Stabilarsan; the arsenical content of the dose stated on the label equals that of the same dose of neoarsphenamine. (vi) Silver arsphenamine. (vii) Neosilver arsphenamine.

All the above compounds except the diglucoside are in powder form, sealed, in stated doses, in glass ampoules containing a neutral gas. All the powders except the silver preparations are yellow. All oxidise and become increasingly toxic on exposure to air and must consequently be made up and administered as soon as possible after the ampoule has been opened. Oxidation in the ampoule, through a flaw in the glass, makes the powder become darker and sticky. Stabilarsan is in solution and ready for use when drawn from the ampoule. It must be used before the expiry date stated on the label.

Arsphenamine is therapeutically the most active of these compounds, but is little used outside U.S.A. because of the complexity of its preparation for administration and of its greater tendency to cause serious reactions on the day of injection. Sodium salvarsan is not greatly used in English-speaking countries.

Neoarsphenamine is by far the most commonly used of all the arsenobenzene compounds. In equivalent dosage it is less active than arsphenamine, but is more easily prepared for administration and causes less general reaction. It causes too much pain to be given as routine by the subcutaneous or intramuscular route, but when it is administered in this way it is therapeutically more active. This is probably because the subcutaneous route favours more the retention of the remedy in the body, thus giving better opportunity for the formation of the derivative which is believed to be the spirochæticidal agent.

Sulpharsphenamine was introduced by Lehnhoff-Wyld under the name of Sulfarsenol for injection by the intramuscular or deep subcutaneous route. It causes comparatively little discomfort when administered in this way. Being relatively stable, its action is inferior to that of neoarsphenamine when

it is given intravenously, and even when administered subcutaneously its effect is barely equal to that of neoarsphenamine given intravenously. It is rather more apt than are the other arsenobenzene compounds to cause blood dyscrasias.

Arsphenamine diglucoside is a convenient preparation in being ready for use when drawn from the ampoule, but its immediate effect in causing disappearance of *S. pallida* from the juice of early lesions is not so great as that of neoarsphenamine in equivalent dosage. A dose of 0·45 g. of a good brand of neoarsphenamine will cause *S. pallida* to disappear from such lesions in 24 hours in over 75 per cent. of cases, but, in my experience, even 0·60 g. stabilarsan has failed in this respect in over 50 per cent. of cases. Whether or not this preparation makes up for its slower spirochæticidal action by greater persistence is uncertain. Silver arsphenamine and neosilver arsphenamine are emery-coloured powders. They are more active but also more toxic than the others and are given in approximately half the dosage of the latter. They are useful as a change from neoarsphenamine but are not now greatly used in Great Britain. A newcomer to the market, though originally tested by Ehrlich, is chemically *m*-amino-*p*-hydroxy-phenylarsine oxide and is sold as Mapharside ; it is not subject to the Therapeutic Substances Act. It is claimed for it that it is the same as the active derivative that is formed when any of the above-named preparations is injected into the body and that, being already oxidised, it is stable. Its dose is about one-tenth that of neoarsphenamine. It is still on trial.

Dosage of arsenobenzene preparations.—Doses of the different preparations named vary greatly with circumstances and can be discussed here only in general terms, but guidance for treatment of individual cases will be found below in the discussions on toxic effects, on contra-indications, and on schemes of treatment. A rational approach to the problem of determining an average dose for an adult male with no contra-indication is a consideration of the amount required to bring about disappearance, within 24 hours, of *S. pallida* from the juice of an early syphilitic lesion, such as a chancre, a condyloma or a mucous patch. It is 0·45 g. to 0·60 g. in the case of neoarsphenamine, and is approximately the same for sulpharsphenamine ; these doses correspond to 0·30 g. to 0·40 g. arsphenamine. In the case of arsphenamine diglucoside the dose required to produce the same effect is somewhat higher, but in that of silver-arsphenamine it is only 0·15 g.

In a case of active primary or secondary syphilis it is reasonable to aim to bring about rapid disappearance of *S. pallida* from the juice of external lesions, and when there is no contra-indication in an adult male I commence with 0·45 g. neoarsphenamine. If, in such a case, I have to begin with a lower dose, it is with no illusion as to the effect on the spirochætes. It is well, therefore, that readers should bear in mind that the official dose of neoarsphenamine or of sulpharsphenamine, the only preparations of this kind in the British Pharmacopœia, commences at a level (0·15 g.) which in the case of an adult would not damage the spirochæte. At the same time it should also be borne in mind that in certain circumstances, as in administration of these remedies to cases of cardio-vascular syphilis, this lower dose may be too high. These remarks may serve to illustrate the difficulty of stating a dosage categorically but, as mentioned, sufficient guidance for treatment of individual cases will be found below.

Administration of arsphenamine preparations

Intravenous route.—This is the most usual route. In the case of neo-arsphenamine the dose is dissolved in 2 to 10 c.c. distilled water. Silver-arsphenamines are dissolved in not less than 8 c.c., and stabilarsan is already in solution and requires no further dilution. The solution is drawn into a syringe, which is armed with a fairly fine needle, any of it contaminating the outside of the needle is washed off under the hot water tap, and the point of the needle is inserted into a median basilic or other convenient vein, which should be distended as tightly as possible by fixing an elastic band round the upper arm and getting the patient to grasp a roller bandage. In making the vein-puncture the operator should look along the vein, and steady it with the index finger of the other hand laid on the skin below the site; the eye of the needle should look away from the skin, and its shaft be almost parallel with it. A pull on the piston causes blood to flow back into the syringe when the needle is properly within the vein. The rubber band may then be released (I usually retain it, for reasons given later), and the piston is *slowly* pressed home. After it has been emptied, a little blood is aspirated into the syringe and again injected in order to clear the needle of any solution.

Deep subcutaneous and intramuscular routes. — As already mentioned, arsphenamine remedies have a greater therapeutic effect when administered subcutaneously or intramuscularly, but most cause too much pain, and practically the only one which can be employed for the purpose is sulph-arsphenamine. The dose may be dissolved in distilled water, or in one of the glucose solvents containing local sedatives which are sold for the purpose. In either case as little as 1 c.c. may be used, but 3 or 4 c.c. of the glucose solvent seems to be more effective in preventing local reaction. The technique of intramuscular injection is described on p. 216. Deep subcutaneous injection causes less muscle reaction, and is usually preferable; it is given as follows: In the upper and outer quadrant of the gluteal region the skin and fat are pulled away from the underlying fascia, by grasping them with the thumb and fingers of the left hand, and a 2-inch record needle is entered obliquely at the base of the pyramid thus produced. The needle is made to underrun the fat so that its point may scrape on the fascia overlying the gluteal muscles. The charged syringe is fitted to the needle and the injection given fairly slowly. The site is then massaged with a pad of lint.

Toxic effects of arsphenamine remedies.—Local.—An intravenous injection of any arsphenamine preparation may cause thrombosis of the injected vein; this is not serious, but precludes the use of the vein for subsequent injections. Escape of any of the solution around the vein causes agonising pain, and swelling and infiltration of the tissues, which may go on to sloughing. When it occurs nothing appears to mitigate it better than such local and general sedatives as are used in any local inflammation.

General.—All these compounds tend to damage capillary endothelium. In patients who have died as a result of arsphenamine injections, there have been found blockage of cerebral capillaries with small hæmorrhages around; hæmorrhagic nephritis; hæmorrhage into lung alveoli; submucous petechiæ and ecchymoses in the stomach and bowel; and, in a comparatively few cases, degeneration of liver cells amounting to a condition like that found in acute yellow atrophy.

Clinically, toxic effects are manifested by one or more of the symptoms enumerated below. The list is a comparatively long one, but most of the symptoms are so mild, infrequent, or preventable as not to preclude the routine use of these remedies. In roughly chronological order they are as follows:

1. *During or immediately after the injection.*—(1) Vasomotor disturbances, also known as anaphylactoid symptoms or minor nitritoid crises; (2) urticaria; (3) syncope; (4) pain in the gums and teeth.

2. *Following the injection usually in a few hours,* and occurring generally on the same day.—(5) Rigor, rise of temperature, and headache; (6) vomiting, diarrhœa, pain in the back and cramp in the legs; (7) herpes (labialis or zoster).

3. *At various times from a day or two to a month or longer* after a single injection or a course of injections.—(8) Albuminuria; (9) stomatitis; (10) chronic headache; lassitude; loss of appetite, weight and sleep; (11) erythema and dermatitis; (12) jaundice; (13) severe cerebral symptoms; (14) various blood dyscrasias; (15) polyneuritis; (16) increase of syphilitic signs and symptoms (Jarisch-Herxheimer reaction).

The *vasomotor symptoms* simulate those of anaphylaxis. The face becomes flushed, and the tongue and lips may swell; there may be respiratory distress, and the patient may become unconscious. Often a severe attack is followed by more or less generalised *urticaria*. As a rule the symptoms last for about half an hour, but in rare cases recovery is not complete for a number of hours. Some patients are peculiarly susceptible. In others the symptoms may be produced by imperfect preparation of the remedy for injection or too rapid administration, as they depend on the physical state of the solution on entering the circulation. For prevention, all these remedies should be injected slowly, and retention of the tourniquet during the injection, as recommended by Sicard, is very effective. The treatment usually employed is to inject 10 to 15 minims of solution of adrenaline hydrochloride (1 in 1000) hypodermically. A feeling of *faintness* during the injection, or immediately after it, may be merely a precursor of vomiting, or due to fear. Occasionally, however, it may be very severe, fatal cases having been reported. Usually syncopal symptoms yield to ordinary restoratives; in some very threatening cases immersion in a hot bath has been reported to have brought about rapid recovery. *Pain in the gums and teeth* is probably vasomotor. The *peculiar taste in the mouth*, of which some patients complain during the injection, is a very common symptom when concentrated solutions are given.

Rigor, rise of temperature and *headache* are commonest after the first injection. The temperature is only rarely over 101° F. and is of no importance unless it increases after each successive injection. *Diarrhœa* and *vomiting* are not frequent unless there has been an error in technique, or the patient has been indiscreet in his dietary. Usually these symptoms have all disappeared by the next day. They are prevented to some extent by taking care that the patient has fasted for 2 hours before the injection.

Albuminuria very rarely causes any anxiety. *Stomatitis* is not often attributed to arsphenamine remedies, but these undoubtedly seem to increase the tendency to this complication which is manifested by patients on mercurial, or bismuth treatment. *Chronic headache, lassitude,* etc., are symptoms

of intolerance displayed by a few patients, and indicate the necessity of a rest from treatment.

Various *skin affections* may occur besides the urticaria and herpes mentioned above, and may be very serious. The mildest is some slight itching which quickly passes off. Another form is Milian's erythema of the ninth day. It appears from the seventh to twelfth day after the commencement of the treatment and within ½ to 2 days of an injection. It is ushered in with a rapid rise of temperature, to 101° F. or higher, headache, backache, and sometimes vomiting and diarrhœa. The temperature is intermittent for a few days, and ends with a generalised scarlatiniform, rubeoliform, or polymorphic eruption, which fades in a few days with very slight or no desquamation. In its prodromal fever and the subsidence of a generalised rash without desquamation in a few days Milian's erythema differs generally from the more serious type described next. Although it is said that arsenical treatment can be resumed after subsidence of ninth-day erythema, it is well to be very cautious on this point. The most severe dermatosis is relatively uncommon. It starts as a punctiform erythema which quickly spreads over the body, is accompanied by most intense itching, and often then passes on to exfoliative dermatitis. The incidence of dermatitis depends largely on the intensity of the treatment. Generally speaking, a male adult of average build will tolerate 5 to 6 g. neoarsphenamine in doses of 0·45 to 0·75, or the equivalent of this in other arsphenamine remedies, spread out over a period of 57 days but if this period is shortened the percentage of dermatitis increases noticeably. A careful look-out for signs of skin irritation will often supply timely warning of the idiosyncrasy and, by preventing the administration of more arsenic, will save the patient from a severe attack. The treatment of exfoliative dermatitis following arsphenamine injections is often troublesome on account of the generalised exfoliation and the local pustulation and eczema. If the attack is at all severe, the patient should be in bed and well protected. The injection of calcium thiosulphate, or sodium thiosulphate, which is now sold for the purpose in ampoules containing the remedy already in solution, has proved to be very useful in aborting the toxic effects of arsenic, bismuth and mercury. The dosage for general use is 0·6 to 0·9 g., injected intravenously very slowly every other day. The injection of calcium thiosulphate often causes a generalised tingling and flushing of the skin, which alarms the patient but passes off very quickly. On intervening days an intravenous injection of 25 c.c. of a 40 per cent. solution of dextrose is valuable. The administration of liver, on the same principles as in anæmia, has been found very beneficial. The diet should be simple, containing large quantities of bland liquids, and should not include eggs and meat. Locally, calamine lotion and liniment are soothing, and an occasional bran bath is valuable, but careful precautions should be taken against chill, as these patients are very prone to pneumonia.

Jaundice following injections of arsphenamine preparations appears to have become more common in recent years, and a voluminous literature on its ætiology has accumulated in all countries without any definite consensus of opinion having been arrived at. In the very great majority of cases the type is mild, with clayey stools and highly coloured urine. Occasionally it is much more serious, with severe epigastric and hepatic pain, restlessness and delirium, followed by death. The changes found in these rare cases have

been extensive degeneration of liver cells with round-celled infiltration of the supporting connective tissue, multiple subserous hæmorrhages, and frequently hæmorrhages into lung alveoli. Either type may occur during a course of injections or be delayed for many months afterwards. In this delay in onset, as in some other features, the fatal type of jaundice strongly resembles trinitro-toluene poisoning. The exact part played by arsphenamine in the production of jaundice is uncertain, but the weight of evidence seems at present to favour a connection between the amount administered as routine in a given time and the proportional incidence of jaundice, the more concentrated the course the higher being the percentage of jaundice. A feature of the fatal type of jaundice which has been noted in this and other countries is its tendency to occur in limited outbreaks which bear no apparent relation to changes in technique or brand of the remedy employed. This feature lends some support to the theory, held by some, that besides arsphenamine an extraneous agency (bacterial infection ?) plays a part in the causation. This view is supported by evidence furnished by Ruge from the German Navy, in which it was found that the incidence of salvarsan jaundice was closely parallel to that of ordinary catarrhal jaundice in the general population.

For the *prevention* of jaundice, apart from the value of care in dosage, clinical evidence suggests that the well-fed patient is far less likely to suffer from this complication than is the starved one. Recent work by Messinger and Hawkins shows that, contrary to the finding of Craven, the best preventive is a protein diet and after this a carbohydrate. For treatment, besides reduction of the diet to slops, administration of liver and daily intravenous injections of 25 to 50 or more c.c. of a 40 per cent. solution of dextrose are useful.

Severe *cerebral symptoms*, with headache followed by mental confusion, epileptiform convulsions and coma, ending in death in a large proportion of cases, are now very rare, thanks to the moderate doses with which treatment is usually begun. One patient, whom I saw in the comatose condition, was restored within half an hour by phlebotomy to 20 ounces, the removal of 15 c.c. of cerebro-spinal fluid, and the injection of 1 c.c. of solution of adrenaline hydrochloride 1 in 1000. Other workers have since been equally successful by this means. The treatment should be applied at once, and the lumbar puncture should be repeated if the symptoms continue.

Blood dyscrasias.—Three main forms of blood dyscrasias have been described, all of them very rare. They have followed sulpharsphenamine treatment relatively much more often than treatment by other arsphenamine preparations. They are thrombocytopenia, granulocytopenia, and aplastic anæmia. When any occurs it is often associated with the dermatitis and stomatitis. Their symptoms and treatment are described elsewhere in this work.

Polyneuritis has been reported occasionally but must be extremely rare; I have seen only one case, a very mild one.

Jarisch-Herxheimer reaction.—A temporary effect of these, as of other antisyphilitic remedies, may be to increase the intensity of the syphilitic process. This may be important when an artery supplying some vital organ is already partly blocked; then the increase in severity of the process may result in a complete blockage which may be disastrous, as when a coronary

artery becomes obstructed, or the patient develops hemiplegia, or dies of obstruction of the basilar artery. Such cases are very rare.

Neuro-recurrences.—Though not strictly a direct effect of arsphenamine treatment, paralyses of various cranial nerves, especially the seventh and eighth, became more common shortly after its introduction. These phenomena have been proved to be syphilitic recurrences and due to the small amount of treatment given in the early days of "606." Since then they have become comparatively rare, at any rate, when bismuth or mercury is given concurrently with the arsphenamine preparation in all early cases.

Precautions recommended in treating patients with arsphenamine preparations.—In the case of sufferers from hepatic and advanced Addison's disease, bleeders, and those on the point of death from severe visceral disease of any kind, these remedies are contra-indicated.

In visceral disease of a less severe type than is mentioned above, in alcoholism, and when the patient is prone to such skin affections as eczema and severe seborrhœa, it is advisable to begin with a dose of 0·15 to 0·3 g. of neoarsphenamine, and to increase the doses with caution; often in such cases the injections of small doses may be given with advantage twice weekly. The same applies to patients suffering from syphilis of the brain, cord or viscera when there is reason to fear an exacerbation of the process. In diabetes mellitus it is necessary to be very cautious, as arsphenamine compounds increase the blood sugar, and the patient should be watched carefully by some one experienced in the administration of insulin. Every patient should be watched carefully through the course for signs of intolerance. This precaution may not absolutely prevent severe side-effects, but such as do develop will usually be much milder than when no notice is taken, for example, of an erythema, and the treatment is continued to the end of the course.

In all cases where intravenous injections are employed it is advisable for the patient to fast for 2 hours beforehand. Other methods of prevention of this and other toxic effects of arsphenamine consist in scrupulous care over technique.

Pentavalent arsenical remedies.—The principal remedies of this class used in the treatment of syphilis are (i) Sodium N-phenylglycineamide-*p*-arsonate (tryparsamide); (ii) 3-acetylamino-4-hydroxyphenyl-arsonic acid, or acetarsol (kharophen, orarsan, spirocid and stovarsol); (iii) the sodium salt of (ii); and (iv) the diethylamine compound of (ii) (acetylarsan).

Of these, tryparsamide is the most important because of its value in syphilis of the central nervous system. It is a white powder easily soluble in water, and the dose for an adult is from 2 to 4 g. (usually 3 g.) dissolved freshly in distilled water and injected intravenously once a week. A course lasts 10 to 12 weeks, and the interval between any two courses can be a month or six weeks. The main risk is of amblyopia, and for this reason the patient's eye-grounds should be passed by an ophthalmologist before treatment is started. If this is stopped on the first complaint of haziness of vision, permanent restriction of vision is very rare. Acetarsol was introduced in 1922 primarily as a prophylactic of syphilis for administration by mouth. Later it came into extensive use for the treatment of infants with congenital syphilis. Acetarsol-sodium and acetylarsan are given by injection; their effects are mainly like those of acetarsol. Toxic effects are usually mild. Acetarsol

can cause gastro-intestinal disturbance if taken too near a meal. Sometimes a mild erythema occurs and very rarely a severe dermatitis.

Mercurial preparations.

Mercury was formerly the sheet-anchor in the treatment of syphilis, but for routine work it has been largely superseded by bismuth, and it is now used mostly in cases where injections are undesirable, or impracticable, or by way of varying the attack on the disease. A great advantage of mercury, as of bismuth, is that it can be kept almost continuously in the circulation, so that the action is maintained after the arsphenamine has been excreted until it is safe to administer another such injection. To ensure the certain destruction of all the parasites, it seems to be necessary that an anti-syphilitic remedy should be present constantly in the body fluids for a long period.

Methods of administration of mercurial preparations.—The *oral method* is much favoured, but is apt to cause gastro-intestinal disturbance, and is exposed to the risk of failure through the patient's forgetfulness. I employ it only when the patient cannot take injections or inunctions and also when the patient cannot continue injections or remain under close observation. Favourite preparations are—(1) Hydrargyrum cum creta, grs. 1 to 2; (2) hydrargyri iodidum viride or flavum, gr. $\frac{1}{6}$ to $\frac{1}{4}$; (3) hydrargyri perchloridum, gr. $\frac{1}{8}$; (4) hydrargyri tannas, gr. 1 to 3; (5) pil. hydrargyri, grs. 1 to 3; (6) liq. hydrargyri perchloridi, min. 30 to 60, often prescribed in a mixture with potassium iodide. The first five of these are usually given in pill form, often combined with a little opium, *e.g.* pulv. ipecacuanhæ et opii grs. 1 to 2, or extractum opii gr. $\frac{1}{8}$, to counteract the irritant effect, but it is better to prescribe the sedative separately, and regulate its dosage as required. I prefer to start with the iodide. A good plan of administration is to give courses of 6 weeks, gradually increasing the daily intake of mercury until slight signs of stomatitis appear, and then reducing the dose. After the first and second courses rests of a week are given, and at the end of the third the interval is one month, after which the series of three courses is repeated. The length of time over which this treatment is prolonged depends greatly on the amount and character of the previous treatment.

Inunction.—This is a valuable method of administering mercury, but must be carried out by a skilled rubber, and has the inconvenience of soiling the skin and clothes. On successive days 5 to 10 g. of mercurial ointment (B.P.) are rubbed for twenty minutes into thighs, calves, arms, chest and back, a bath being taken on the sixth day and the cycle restarted on the seventh. The number of rubbings varies from 60 to 200 in a course, the length of a course depending on the patient's tolerance, which is judged by the state of the gums, the weight and the general well-being.

Intravenous injections are rapid in effect, but apt to cause toxic symptoms; they have the further disadvantage that the effect is not sustained, and must be administered daily or every other day. The usual preparations employed are the cyanide and the perchloride, in doses of 1 c.c. of the 1 per cent. solution daily or on alternate days to a total of twenty or thirty.

For *intramuscular injections* both soluble and insoluble preparations are employed. Among the *soluble* preparations are the biniodide (1 per cent. solution) in doses of 1 c.c., the bibromide, the benzoate and the perchloride. Their disadvantages are similar to those of intravenous injections.

The *insoluble* preparations most commonly employed are mercury in fine subdivision (inj. hydrargyri), calomel (inj. hydrarg. subchlor. and mercury salicylate. Suspensions of these remedies ready for use can be purchased. The doses usually employed are: mercury, 1 to 1½ grs.; calomel, ½ to ¾ gr.; salicylate, 1½ to 2 grs. Calomel causes more pain than the other two, but is far more active, and is probably the best for this purpose if it can be tolerated. Mercury salicylate is probably the least active of the three. The advantages of the insoluble preparations are that, on account of the slow absorption, enough mercury can be given in one injection to last a week and that the effect is sustained.

The technique of intramuscular injections is simple. The best site is the upper and outer quadrant of the gluteal region. A needle 1½ to 2 inches long is introduced, almost to its full length, perpendicularly to the skin surface. The base is examined to see that no blood is oozing from it, the syringe is applied, the piston pulled upon to see that the needle point is still not within a vein, and the piston is then pressed home. The needle, having been withdrawn, the site is well massaged with a ball of cotton-wool. Before an insoluble preparation is drawn into the syringe, the suspension should have been well mixed, either by stirring with a glass rod or by energetic shaking of the bottle.

Toxic effects of mercury.—These are stomatitis, nephritis, colitis, general malaise and dermatitis.

Stomatitis can usually be prevented by care. The patient's teeth should be set in order before starting the course, and he should brush his teeth night and morning; the tooth brush should be kept in an antiseptic solution, such as chloramine T., 0·5 to 1 per cent., or in an atmosphere of formalin. Potassium chlorate is useful, and may be incorporated in the dentifrice. If the gums become sore, the mercury must be stopped and more energetic treatment applied to the mouth. Lozenges of potassium chlorate to suck, and swabbing with peroxide of hydrogen followed by the application of a 10 per cent. solution of neoarsphenamine usually suffice to restore the gums to a healthy condition. An astringent mouth-wash should be employed and injections given of calcium or sodium thiosulphate. (See p. 212.)

Nephritis rarely results from the moderate doses of mercury now employed, but the irritant effect of mercury on the kidneys should be remembered in cases where these organs are already diseased.

Colitis is extremely uncommon as the result of the ordinary mercurial course of treatment. *General malaise* is apt to result from pushing mercury too freely, and it is always advisable to keep a close watch on the patient's weight and general condition. *Dermatitis* as a result of mercurial treatment alone is very rare.

Bismuth preparations.

These were introduced by Sazerac and Levaditi in 1921, and have now largely supplanted mercury wherever the intramuscular, or deep subcutaneous, route of administration is practicable. Bismuth is tolerated better than mercury, and in doses which can be administered with at least equal safety, a course of bismuth injections goes farther towards eradicating the disease than does a corresponding course of mercurial injections. Some workers assert that bismuth is equal in effect to the arsphenamine preparations, but

the majority opinion is that it should be used in conjunction with these, in substitution for mercury. The toxic effects of bismuth are somewhat similar to those of mercury. The first sign of saturation is a slaty-blue line at the margins of the gums, particularly at the incisor teeth. If the remedy is continued, the buccal mucous membrane may become stained, and aphthous stomatitis supervene; if it is pushed still farther, gangrenous stomatitis may result. The early bismuth blue line may persist for many weeks after suspension of the remedy. Albuminuria may result from overdosing, but disappears quickly if the remedy is suspended as soon as it is noted. Colitis is uncommon. Some may complain of depression and insomnia, which may easily be attributed to other causes than bismuth poisoning.

Bismuth is at present administered almost exclusively by injection, but recently a preparation for oral administration has been introduced by Hanzlik, Lehman and Richardson. It is sold under the name of sobisminol, and has been reported to give good results in doses of 6 capsules of 0·75 g. daily. So far it must be regarded as in the experimental stage and will not be dealt with further.

Injection of bismuth compounds is now almost invariably by the intramuscular or the deep subcutaneous route, and the number of preparations is legion. They are best classified on the basis of rapidity of absorption as follows: (*a*) watery solutions; (*b*) solutions in oil (lipo-soluble preparations); (*c*) suspensions of insoluble compounds in a watery medium; and (*d*) suspensions of insoluble compounds in an oily medium. The comparative rates at which these different classes of bismuth preparations are absorbed are in the above order.

Watery solutions are not greatly employed now, because they are more rapidly absorbed than is usually convenient; on account of rapid absorption, their toxic effects may approach those of preparations given intravenously, a route which is practically never used. Examples of water-soluble compounds are: potassium sodium bismuth tartrate, containing 35 to 40 per cent. Bi.; bismuth sodium tartrate, containing 73·8 per cent. Bi.; bismuth thioglycollate, sold as thiobismol, a solution which contains 0·075 g. Bi. per c.c.; and sodium bismuth citrate, containing 65·8 per cent. Bi. Because of the rapidity of their absorption, an effective concentration of bismuth in the tissues can be maintained with watery solutions of bismuth only by injecting them two or three times a week.

Oily solutions contain organic, lipo-soluble compounds dissolved in oil. In absorbability they are stated to be a useful medium between watery solutions on the one hand and insoluble suspensions on the other. The following are examples of these preparations of which it is unnecessary to state the chemical formulæ (the bismuth content per c.c. is stated in brackets after each): bivatol (0·035 g.); cardyl and neocardyl (0·05 g.); neo-olesal (0·03 g.); and stabismol (0·1 g.). Their rate of absorption makes it advisable to give the weekly dose (see below) in two injections at a 3- to 4-day interval.

Insoluble suspensions are the most commonly employed preparations of bismuth for anti-syphilitic treatment, and this class contains the only three recognised by the British Pharmacopœia, namely, inj. bismuthi, inj. bismuthi oxychloridi and inj. bismuthi salicylatis. A number of insoluble salts of bismuth are used, and they are sold under a large number of names, of which the following are examples arranged according to their chemical

construction. (*a*) Precipitated bismuth. Preparations: inj. bismuthi, B.P. (bismuth in a dextrose solution with cresol), and bisglucol; both contain 0·2 g. Bi. per c.c.; and bicreol (0·15 g. Bi. per c.c.); (*b*) Bismuth oxychloride. Preparations: inj. bismuthi oxychloridi, B.P. and bisoxyl, both of them watery suspensions containing 0·08 g. Bi. per c.c.; chlorostab, a watery suspension, two preparations with, respectively, 0·16 g. and 0·20 g. Bi. per c.c.; (*c*) Bismuth salicylate. Preparations: inj. bismuthi salicylatis, B.P., a 10 per cent. suspension of the compound in olive oil with camphor and phenol; bisantol; bismosan; bismogenol, all oily suspensions; all this class contain about 0·06 g. Bi. per c.c.; (*d*) Bismuth hydroxide. Preparations: casbis, muthanol, and spirillan, oily suspensions containing about 0·08 g. Bi. per c.c.; (*e*) Iodo-bismuthate of quinine. Preparations: biquinyl; bismosalvan; quinby; quinostab; rubyl; vijochin, all oily suspensions containing about 0·02 g. Bi. per c.c.

Choice of bismuth preparations.—In syphilis with active external manifestations and when there is no contra-indication in the nervous system, the heart, and great vessels or other internal organs, we aim at complete eradication of *S. pallida* by attacking it over a long period with two types of remedy, namely, arsphenamine and heavy metal, the latter being either mercury or bismuth, of which bismuth is now almost always preferred. In this combination the arsphenamine compound rapidly stops the activity of *S. pallida*, and each injection of it deals a heavy blow at all *accessible* spirochætes, but the attack is not maintained; the dose of the arsphenamine preparation is quickly excreted, and for a considerable portion of the interval between any two injections, and still more between any two courses of injections, the arsenical remedy is not in action. In these circumstances it is conceivable that spirochætes not hitherto destroyed by the arsphenamine remedy, perhaps because of their entrenchment behind barriers of fibrous tissue, would have an opportunity of recovering unless the attack was carried on by another agent. This is the rôle of the heavy metal, an effective concentration of which can be maintained in the tissues for long periods. It will be understood from the above that, if an arsphenamine preparation is being employed in the treatment of the types of syphilis mentioned, one does not look to the bismuth for speed, but for persistence of action, and a preparation is needed which is absorbed slowly but steadily throughout the intervals between injections; this requirement is met by the use of a suitable insoluble compound. In the choice of such a compound, I am influenced by clinical experience and by reports of research on absorbability of different preparations, especially those of Lomholt, and prefer a compound such as the oxychloride suspended in a watery medium to either of the other two B.P. preparations. In some cases I have been convinced that the precipitated bismuth I have injected has not been absorbed at all satisfactorily, and excretion experiments which show that a higher percentage of a small dose than of a large one are absorbed in a given time argue against the employment of such a concentration of bismuth in the suspension as that in the injectio bismuthi, B.P. Between the salicylate or any of the other insoluble salts and the oxychloride there may possibly be little to choose, but Lomholt's experiments on absorption certainly showed that, other things being equal, a more rapid absorption would follow injection of a watery suspension than that of an oily one, such as injectio bismuthi salicylatis, B.P. On the other hand, the oxychloride is pure and stable

and in watery suspension, provided it is not too finely powdered (particles of 3 to 5 μ dimensions are suitable), it is absorbed at a satisfactory rate without causing undue discomfort. This work confirms the favourable impression I have formed of the oxychloride in watery suspension in an experience of more than fifteen years.

A quicker absorption of an insoluble compound is secured by giving the weekly dose in two injections at an interval of 3 to 4 days, or by dividing the dose between two sites injected at one sitting. In some cases it may not be possible to employ an arsphenamine preparation at all, or only in less than efficient dosage, and one has to depend more on the bismuth to stop the spirochætal activity quickly. In such a case one may give one of the oil-soluble preparations twice a week or proceed on the lines recently recommended by Sollmann and colleagues in U.S.A. In this a soluble preparation is administered two or three times weekly concurrently with an insoluble one once weekly for 5 or 6 weeks, and then the insoluble preparation is continued in weekly injections for 5 more weeks to complete the course.

It will be judged from the above that usually an insoluble compound is injected about once a week, and a soluble one, two or three times. One insoluble compound, however, the iodo-bismuthate of quinine, which is not greatly used in early syphilis, but is valuable in cardio-vascular and neuro-syphilis, contains such a low percentage (20) of bismuth that the dose is contained in a large volume; consequently when employing this compound it is customary to give the weekly amount of bismuth in two injections. This compound is absorbed rather more quickly than most others in the insoluble class. In certain cases one may have reason to fear that the patient might become seriously intolerant, and it may not be desirable that the remedy should continue to be absorbed for long after suspension of the treatment. It would then be advisable to proceed cautiously with an oil-soluble preparation.

In average cases of primary and secondary syphilis I give bismuth concurrently with arsphenamine preparations, believing that when the latter are used alone at the commencement and in such doses as effectually to stop the interaction between parasite and skin, there is a much greater likelihood of the parasite getting a footing in the central nervous system. In this matter of concurrent arsphenamine with bismuth and of alternating arsphenamine courses with bismuth ones, there is a difference of opinion amongst syphilologists, probably the majority in Great Britain believing in the concurrent plan. My own views are based largely on the facts that in the early days of arsphenamine treatment, when great reliance was placed on the administration of "606" *in full or nearly full doses* without the concurrent administration of mercury, syphilitic neuro-recurrences were common, and that in more recent years in certain clinics where the first course of treatment consists entirely of arsphenamine or neoarsphenamine in such doses as we know rapidly bring about the disappearance of *S. pallida* from the secretion of superficial lesions, the incidence of such neuro-recurrences has also been high. Certain clinics in which the alternating plan is followed have not had this experience, and the explanation of the difference may lie in the dose of the arsphenamine preparation. If the dose of arsphenamine used alone in a first course given to an early case of syphilis is not so high as that mentioned above, it may be that the interaction between skin and parasite continues, and so evokes an

immunity response which prevents the spirochæte from stimulating a big enough reaction in the meninges to cause symptoms.

Iodine preparations.

These promote the resolution of syphilitic processes and are most useful in the later stages. The tissue reaction is qualitatively the same in all stages, however, and there are grounds for supposing that the syphilitic infiltrate tends to bury the parasites, making them inaccessible to anti-syphilitic remedies, so that there is a use for iodine preparations in all stages. The favourite preparation is potassium iodide, in doses of 15 to 30 grains thrice daily. It may cause gastro-intestinal disturbance, even when given very dilute in water, and is then better tolerated if made up in a cent. per cent. solution and the dose dropped into milk. The depressing effect of potassium iodide is overcome by giving it with nux vomica. Many proprietary preparations are advertised as superior to potassium iodide, but they should be reserved for cases where the older preparation cannot be tolerated. Sodium iodide is probably the best preparation for intravenous injection. In this case, after testing the patient's tolerance by giving some potassium iodide by mouth, a dose of 150 grains of sodium iodide dissolved in 100 c.c. or more of sterile distilled water is given intravenously every 24 to 48 hours up to a total of 20 to 30 injections per course.

General management of syphilis.

The main principles to be observed in the treatment of syphilis are—(1) to begin as early as possible, before the micro-organism has become buried in the sclerosed primary sore or entrenched in comparatively inaccessible regions, such as the central nervous system; (2) to continue as long as experience shows that there is a possibility of the patient relapsing if treatment ceases; (3) to exploit the patient's natural resistance, by maintaining his general health in the highest possible condition.

Since the decision as to cure has to be postponed for some years after suspension of treatment, and relapse cases are particularly difficult to cure, it is better to treat all cases as if they were of the resistant type. It is a great mistake to stop treatment as soon as the serum reactions become negative, or to continue then with only a feeble form of treatment, such as mercury by mouth.

With regard to the programme of treatment to be followed in an ordinary case of early syphilis in a man of average weight *without clinical* signs of disease of the central nervous system or of any viscus, two alternative plans have been recommended by the Committee of Experts on Syphilis convened by the League of Nations Health Organisation; the plans were based on an analysis of over 13,000 records of early cases of syphilis treated in five countries. By early syphilis the Committee meant primary and secondary syphilis such as constitute the vast majority of syphilis cases seen within the first few years of infection, but, with the reservations as to disease of the central nervous system or of any viscus mentioned above, the recommendations are applicable to most cases within the first three or four years of infection. One plan is described as "intermittent treatment," because in it the arsphenamine and the bismuth preparation are for the most part given concurrently, and intervals of three to five weeks are allowed between courses of

injections. Actually its effect is continuous because the insoluble bismuth administered during each course continues to be absorbed during the interval. The second plan is termed " alternating continuous," since for the most part series of arsphenamine injections alternate with series of bismuth, and no interval longer than a week is allowed between injections. In framing both plans the principles laid down by the Committee were :

" (*a*) To employ a comparatively heavy individual dosage of the arsenobenzene and of the bismuth or mercurial compounds, the doses being administered in comparatively rapid succession, especially at the commencement ;

" (*b*) To maintain a persistent attack on the disease, avoiding intervals of such lengths as to afford the parasite an opportunity of recovering ;

" (*c*) To administer approximately as much treatment to primary as to secondary cases."

The plan of " intermittent treatment " prescribes a series of courses as follows, with intervals of three to five weeks between any two courses. In the first seven weeks 8 injections of 0·6 to 0·75 g. neoarsphenamine (or other arsphenamine preparation in equivalent doses) concurrently with the same number of doses of an insoluble compound of bismuth, each containing 0·20 to 0·24 g. metallic bismuth (*e.g.* 0·25 to 0·30 bismuth oxychloride), or else twice the number of injections of a liposoluble compound of bismuth, each containing 0·10 g. metallic bismuth ; in the next two weeks only bismuth is given.

The blood is tested at the end of each course. The minimum number of courses for any case which remains or becomes serologically negative during or by the end of the first course is four. For cases that are not negative by the end of the first course the minimum is three beyond that course which ends with negative reactions. For non-pregnant females the treatment should be on similar lines, with the individual dose of neoarsphenamine reduced by 0·15 g.

In the recommended plan of " alternating continuous " treatment for an adult man, after three doses of " 606 " or alternative arsphenamine preparation totalling 0·1 g. per 25 lb. weight in the first week, 0·4 g. " 606 " is given in each of the 3rd to 7th, 12th to 17th, 24th to 29th, 38th to 43rd, and 54th to 59th weeks, 29 injections in all ; and a bismuth compound containing 0·2 g. Bi. is injected weekly in the 8th to 11th, 18th to 23rd, 30th to 37th, 44th to 53rd, and 60th to 69th weeks, 38 injections in all. Potassium iodide is given during the administration of the bismuth. It is recommended in this plan that the blood be tested on the 1st day and in the 7th, 12th, 13th, 17th, 38th, 43rd, 54th, and 59th weeks ; and the spinal fluid in the 18th to 23rd weeks.

J. E. Moore, who is otherwise an advocate of the alternating system, gives 4 doses of Bi. (0·2 g.) concurrently with the first four of arsphenamine, then continues at weekly intervals with 4 doses of the latter, followed in turn by 4 Bi., 6As., 6 Bi., 6 As., 8 Bi., 6 As., 10 Bi., 6 As., and 10 Bi.

For reasons already given, my strong preference is for the plan of intermittent treatment. For men of average weight a dose of 0·6 g. neoarsphenamine seems to be sufficient, and for pregnant women 0·45 g.

Before suspending treatment the cerebro-spinal fluid should be negative. After suspending treatment the patient should be put under observation, being examined clinically once a month, and by blood test every 3 months for a year. At the end of the year the cerebro-spinal fluid is examined. During the second year the blood tests are at intervals of 6 months, the examination of cerebro-spinal fluid being repeated at the end. As a rule it is not advisable to allow a patient to marry until after 5 years from infection and after remaining free from all signs, clinical and serological, for at least 2 years following suspension of all treatment.

In all cases of primary sore it is very important to apply local treatment to destroy the organisms *in situ*; otherwise they may escape the remedies circulating in the blood. If the sore is indurated and the induration does not disappear quickly under general treatment, it should be removed by circumcision, destroyed with the cautery, rubbed with mercurial ointment or injected with a solution of neoarsphenamine (say, 0·15 g. in 0·5 c.c. water).

In later syphilis, *i.e.* after the third or fourth year, the line of treatment depends very much on the involvement of viscera and/or nervous system, the treatment of which is discussed elsewhere in this work. It is very important in these later cases to examine carefully the cardio-vascular and nervous systems. If the cerebro-spinal fluid is positive, there is little hope of restoring it to normal by ordinary anti-syphilitic treatment. In such cases tryparsamide is probably the best remedy to employ at first. It is given intravenously in weekly doses, commencing with 2 g. for an adult and increasing at once to 3 g., dissolved in 10 c.c. distilled water, in courses of about 10 injections, with intervals of about 6 weeks between courses. The concurrent use of bismuth seems to be advantageous in these cases. Assuming that, as is usual, no sign of optic nerve disturbance appears, patients commonly tolerate very large total amounts of tryparsamide—as much as 10 or more courses. The cerebro-spinal fluid should be examined periodically, and the tryparsamide treatment is continued in regular courses, with intervals, so long as improvement is steady. If no improvement in the state of the fluid is apparent by about the end of the third course, one considers the institution of pyretotherapy, of which probably the most effective form (apart from the use of physical apparatus for production of fever) is malarial inoculation, and usually about ten paroxysms of fever are allowed before interference by means of quinine or some similar remedy.

Both malaria and the use of physical apparatus may be impracticable, as the patient usually feels well and also may be a busy man unable to spare the time for, or perhaps explain to his family the necessity of, entering a nursing home or hospital for a course of malarial paroxysms, or of fever produced by physical agents. For this reason it is usually more practicable to try at first a course of fever induced by simpler means, such as the intravenous injection of a vaccine. The most popular for this purpose seems to be antityphoid vaccine, of which the dose may begin at 200 millions and be increased with successive injections, given every other day, by about 80 per cent. The aim is to provoke a rise of temperature to about 104° F., which is reached a few hours after the injection. The vaccine of the Ducrey bacillus, sold as dmelcos, is perhaps more convenient and less toxic than antityphoid; the first dose is usually 1 c.c., and the dose is increased with successive injections to 5 c.c. or more. The disadvantage of vaccine injections given in this

way is that the patient quickly becomes tolerant, and even large increases of the dosage produce very disappointing results in respect of temperature rise, so that there is much to be said for the method of Nelson whenever it is practicable. In this the patient receives two doses each day, each smaller than would be necessary by the single-dose method, the second being given 2 or 3 hours after the first, when the fever produced by this is at its height; the effect is to flick up the temperature to a much higher level. The scheme shown in Nelson's paper used T.A.B. vaccine. After preliminary single doses of 70 and 140 millions on the first and second days, resulting respectively in temperatures of 103·6° F. and 103° F., on each of the next 11 days two doses were given. The first of these ranged from 25 to 75 millions, and the second was sometimes the same as the first, and sometimes as much as 80 per cent. higher. If the second dose does not produce a sufficient rise, a third given before defervescence may do so. Many workers have now reported well on this method. Another method is to inject intramuscularly a solution of sulphur in oil, such as sulfosin, beginning with 1 c.c., and increasing to 10 c.c., according to the temperature provoked. After the fever treatment it is best to continue with the tryparsamide and bismuth, or with some form of ordinary anti-syphilitic treatment.

For cases of tertiary syphilis affecting the external and supporting structures and for latent ones, when the cerebro-spinal fluid is negative, the first course can usefully be on the same lines as shown above for early cases, while in later ones it may be preferable to rely more on bismuth, giving this entirely, or interspersing a few doses of an arsphenamine preparation. It is well also to administer considerably more iodine to later cases. In these later cases it is often very difficult or even impossible to convert the serum reactions to negative, and many syphilologists will not treat them beyond the stage when they show no clinical signs, maintaining that it is hopeless to convert the reactions, that the treatment only gets on the patient's nerves, and so forth. I am sure that this view is mistaken. Patients with latent syphilis who have not complained of any particular feeling of ill-health commonly remark after the first or second course of treatment that they now feel better than they have done for years; it is as if an insidious depressor of health had been removed. Moreover, it is not true that treatment of these cases has no effect on the serum reactions. If a serum test is employed which measures the strength of reaction in units, the effect of treatment is obvious. Thus, in a case tested by the Sigma method before treatment the reaction may be, say, 36 units; at the end of the first course in such a case it is often 18 or 20 units; at the end of the second course, 8 or 10; and so it gradually becomes reduced to 2 or 3, a number which is still regarded as positive, and at this it is apt to remain, but at this stage a change to mercury by mouth for some months often reduces the strength of the reactions quite remarkably. I usually treat steadily until the figure indicating the strength of serum reaction has not been reduced for two or three courses, and then advise continuation treatment at the rate of about three courses in 2 years.

Pregnant women are treated on much the same lines as early cases, the dose of the neoarsphenamine or the sulpharsphenamine preparation not exceeding 0·6 g. The point of greatest importance in these cases is to prevent the spirochæte reaching the circulation of the fœtus, and this can generally

be done by starting treatment in the first half of pregnancy, the earlier the better, and continuing it almost to the end. On account of the susceptibility of the kidneys, it may be advisable to withhold mercury or bismuth for the first few injections until it is seen how the injections are tolerated.

Syphilitic infants.—The following rules may help in deciding whether or not the infant should be treated, and the lines of treatment in the event of this being necessary:

As already mentioned, it is unsafe to rely on a positive serum reaction for a decision to treat, or on a negative one for a decision to withhold treatment.

(1) *S. pallida* can usually be prevented from entering the fœtus by commencing the treatment of the mother in the first half of pregnancy.

(2) The older the infection of the mother, and the earlier she is treated in her pregnancy, the greater the justification for a "wait and see" policy in regard to treatment of the offspring after birth.

(3) If the mother's syphilis has been treated indifferently and is of less than five years' duration, and if her treatment in this pregnancy was started later than the 4th month, it is safest to treat the offspring.

(4) Either the infant is infected or it is not infected. Precautionary treatment, so called, is given on the assumption that it may be infected and should be as complete as if infection had been proved completely.

(5) CURATIVE TREATMENT.—(*a*) If it is decided to give arsphenamine and bismuth, the scheme of treatment may be on the lines set out in the League of Nations Schedule, giving intramuscularly, 0·02 g. sulpharsphenamine and 0·004 g. bismuth metal per kg. infant (say 0·08 g. sulpharsphenamine and 0·20 c.c. of a 10 per cent. suspension of the oxychloride, or 0·8 c.c. of a similar suspension of the iodo-bismuthate of quinine for an infant weighing 9 lb.). (*b*) In place of sulpharsphenamine it may be more convenient to give acetarsol (p. 214), by mouth. In this case the following, in conjunction with heavy metal, would probably suit most cases. The dose of the drug is given in water half an hour before the first feed. Probably the best scheme of dosage is one based on the infant's weight as follows:

1st week, 0·005 g. per kg. per diem.
2nd ,, 0·010 ,, ,,
3rd ,, 0·015 ,, ,,
4th to 10th week, 0·02 g. per kg. per diem,
4 weeks' rest.

The course of acetarsol and bismuth should be repeated three times after the blood has become negative. (*c*) Instead of bismuth treatment shown in (*a*) and (*b*), inunctions with mercury ointment (15 to 60 grains of the B.P. preparation, according to age) can be given daily throughout each course except in the fifth week, or yellow mercurous iodide $\frac{1}{8}$ grain dropped into the milk three times a day.

In older children and adults with congenital syphilis the treatment is on similar lines to those employed in corresponding stages of acquired syphilis, but there is here probably more reason to supplement the injection treatment by pyrogenetic measures.

Needless to say, the hygienic conditions of the patient must be such as are likely to raise his general resistance to infection.

L. W. HARRISON.

YAWS

Synonyms.—Framboesia; Framboesia tropica; Pian; also many vernacular names such as Parangi (Ceylon), Bubas (Brazil), Coco (Fiji), etc.

Definition.—A contagious, inoculable, tropical disease caused by *Treponema pertenue*. The primary lesion is of non-venereal origin and is followed by the secondary stage consisting of an eruption of typically granulomatous papules. The tertiary stage, occurring a few or many years later, is characterised by destructive lesions.

Ætiology.—Yaws is essentially a disease of indigenous populations of tropical countries. Europeans are rarely affected. It is prevalent in the West and East Indies, Ceylon, the Philippines, Oceania and New Guinea, and parts of tropical Africa and South America. It is only present in a few isolated communities in India. Infection usually occurs in childhood, although a few adults escaping infection then may contract it later, often from their own infected children. The disease is not transmitted congenitally, and infection is generally regarded as occurring only once in a lifetime. Both sexes are attacked. The cause is the *T. pertenue* (Castellani, 1905), which is morphologically indistinguishable from the spirochæte of syphilis; on animal inoculation, however, constantly different reactions have been observed by a number of observers. Animals infected with either of these organisms become resistant to inoculation with the same spirochæte earlier than to that with the other. This is probably true also in the case of man. The similarity of yaws and syphilis is greatest in the tertiary stage. Although some authors regard these diseases as identical, the present state of knowledge does not warrant this. Bejel, the non-venereal syphilis of the Bedouin Arabs, has certain epidemiological and clinical similarities to yaws. *T. pertenue* enters the skin through minor abrasions, cuts or previously existing ulcers, most commonly on the limbs and especially the legs. It is possible that some insects may transport the Treponemata and thus spread infection.

Pathology.—The primary and secondary lesions are characterised by interpapillary down-growths of epidermis into the corium. There is also œdema and infiltration with polymorphonuclear leucocytosis and plasma cells both in the proliferated epidermis and in the corium. Spirochætes are more numerous where the cellular infiltration of the epidermis is most pronounced, but they are also present in the adjacent corium. The tertiary lesions are characterised by necrosis and ulceration with granulation tissue and dense fibrous tissue. Giant cells are frequently present, but spirochætes are not numerous. Peri-vascular cellular infiltration and vascular endothelial proliferation are usually said not to occur in yaws lesions, but recent work indicates that there are no generally reliable histological criteria for the differentiation of yaws and syphilitic skin lesions.

Symptoms.—The incubation period in man is 4 weeks or longer (in monkeys 3 weeks), and may be accompanied by mild general symptoms.

The primary lesion, which is not always demonstrable, resembles the typical secondary lesions but is often larger. It is usually single and extragenital, and may heal before the secondary eruption appears or outlast it. The adjacent lymphatic glands may be enlarged.

The *secondary stage*, which may appear within 3 weeks of the primary

lesion, may be heralded by irregular intermittent fever, headache, bone and joint pains, often worse at night, and a characteristic more or less generalised papular eruption. This commences as small, yellowish papules, which increase in size or coalesce to form larger lesions. The stratum corneum is shed, exposing a granular surface of minute pinkish elevations, separated by a whitish groundwork. Serum containing treponemata exudes and dries, forming a yellowish crust, which later may become discoloured and polished, especially in the case of less active lesions. Pus is not usually present. Healing occurs sooner or later, often leaving but little scarring, although hyperpigmentation, which later disappears, may be seen. The lesions may itch, and, although not very painful, are sensitive to minor irritation, such as flies. The distribution is general, but the trunk is often relatively spared. The body orifices and the soft skin of flexures are particularly involved. Successive crops may appear for from 2 or 3 years. Other types of skin lesion, pathologically related to those just described, are often seen, but usually typical secondary lesions are also present. A fine desquamation is sometimes present, and general enlargement of the lymphatic glands is often found. The eruption of a yaw on the sole, clavos or crab yaws, is particularly painful, and may occur many years after the earlier lesions have healed. Yaws papules may also occur on the buccal mucous membrane. Bone lesions are frequent during this stage, and are characterised by swellings. Periosteal deposits and rarefied foci in these deposits and in the cortex are seen radiographically. Sabre-tibia may develop, but destructive bone lesions do not occur. Multiple dactylitis is frequent. Ganglia and synovitis with free fluid are seen. Goundou belongs to this stage. All secondary lesions heal spontaneously, although bony deformities remain. The general health is not usually seriously affected.

The *tertiary stage* may be reached within a year of the healing of secondary lesions, or after a quiescent period of many years. Lesions at this stage are characterised by tissue destruction and ulceration. In the skin superficial ulceration or deep gummatous-like processes may occur, which on healing leave hyperpigmented atrophic scars and occasionally contractures. In the bones, swellings with ulceration associated with bony necrosis (" gummata "), spontaneous fractures, deformities of the digits, periostitis, nodes, synovitis and arthritis are seen. Destructive processes in the mouth and nose may lead to palatal perforation and to gangosa. Epidermal thickening, erosions, fissures and coarse desquammation occur on the palms and soles, some of which may return to normal, but others result in atrophic changes, pigmentation and contractures of the fingers. Juxta-articular nodes, chronic bursitis and patchy depigmentation of the skin are also met with.

Complications and Sequelæ.—In severe tertiary cases with many lesions, cachexia may result. One or more intercurrent diseases may be present. In Fiji and Haiti aneurysm and lesions of the central nervous system have been attributed to yaws, but the evidence is not convincing.

Diagnosis.—In localities in which yaws is prevalent there is usually no difficulty in diagnosing the early lesions, but congenital and acquired syphilis, bejel and bromide rashes may occasionally call for consideration. Treponemata can usually be found in serum from early lesions. The differentiation of tertiary lesions from syphilis may be impossible on clinical or pathological evidence, and a history of yaws in the past may be the only guide. Cutaneous leishmaniasis, blastomycosis, leprosy and tuberculosis may lead to confusion.

The Wassermann and Kahn reactions are positive in yaws and syphilis after the first few weeks. The absence of mucous patches, visceral, vascular and central nervous system lesions in yaws and its ready response to modern arsenical and bismuth preparations may help to differentiate the two diseases.

Prognosis.—All secondary lesions heal spontaneously in a few months or years, and probably some cases become spontaneously cured and develop a negative Wassermann reaction. Yaws is rarely fatal, most deaths being due to intercurrent disease. Modern therapy is very effective. In tertiary lesions more intensive treatment is required to produce healing and here, too, spontaneous cure probably occurs although less readily.

Treatment.—PROPHYLACTIC.—The recognition of the infectiousness of yaws and ordinary cleanliness are adequate. Cuts, abrasions and ulcers should be covered.

CURATIVE.—Neoarsphenamine and allied drugs are as specific for yaws as they are for syphilis. A single injection may clear up secondary lesions and occasionally even change the Wassermann reaction to negative ; after four or more injections (0·6 g., adult) probably more than 40 per cent. of cases will be cured. Bismuth preparations are much cheaper, but although almost as effective are not so rapid in their action. Intramuscular injections of insoluble bismuth are probably not completely absorbed after 6 months or more (Hackett), and stomatitis and albuminuria may occur. Sodium-potassium-bismuth-tartrate, bismuth oxide (0·2 g., adult), and other bismuth preparations in water or oil may be used ; at least six injections are given once or twice weekly. When feasible, combined treatment is the method of choice. In tertiary lesions potassium iodide is of value. Intercurrent diseases, if present, need treatment.

GOUNDOU

Synonyms.—Anakhre ; Gros Nez ; Dog Nose.

Definition.—Symmetrical bony tumours of the sides of the nose commencing during the secondary stage of yaws.

Ætiology.—This condition is probably to be found wherever yaws is prevalent, but has been reported most often from tropical Africa, especially in the west. It is seen in children and adults. Some reduction in size of the lesions in early cases may occur spontaneously or after treatment.

Pathology.—There is thickening of the periosteum with production of spongy tissue in which are fibrosis and perivascular plasma cell infiltration. The bony tissue is usually bounded by a thin layer of cortical bone. This hypertrophic osteitis involves the nasal process of the superior maxilla. In marked cases the tumour may encroach upon the nasal passages, orbit, or palate.

Symptoms.—Osteocopic pain, headache, and a thin blood-stained purulent nasal discharge may occur in the early stages, but later these subside. The paranasal swelling on one or both sides increases outwards, and may become large enough to obstruct vision. Facial deformity may be the only symptom, but nasal obstruction may result from extension to these passages. The over-lying skin is not implicated. Sometimes similar tumours elsewhere on the superior maxilla, or on the inferior maxilla, and other yaws bone lesions may also be present.

Diagnosis.—In yaws communities the paranasal swellings are characteristic, but in isolated cases differentiations may be needed from syphilitic osteitis, leontiasis ossea, and possibly acromegaly.

Prognosis.—Though it may be distressing, the disease rarely causes death.

Treatment.—Energetic anti-yaws therapy is indicated in early cases, and surgical removal of the bony tumour in advanced ones.

Gangosa

Synonym.—Destructive Ulcerating Rhino-pharyngitis.

Definition.—An ulcerative process of tertiary yaws resulting in destruction of the palatal and nasal structures.

Ætiology.—This condition is probably to be found wherever yaws is endemic. Its presence in the Pacific Ocean Islands and the East Indies has been stressed. It may commence in older children and adults.

Pathology.—The process begins with ulceration of the palate or in the nose, and is followed by destruction of soft tissues and bone. The histopathology is that of tertiary yaws.

Symptoms.—Pain, purulent discharge and foul odour accompany the ulceration mentioned above. The amount of destruction produced varies from a small perforation of the soft or hard palate, or some falling in of the nose to complete destruction of the palate, nose, nasal contents, and adjacent tissue of the cheeks and orbit so that the roof of the nasal cavities, pharynx and tongue are exposed. Arrest of the process, either spontaneously or following therapy, may occur at any stage. The larynx is probably not affected.

Diagnosis.—In yaws communities this is usually easy, but differentiation from American dermal leishmaniasis, syphilis and leprosy may be necessary.

Prognosis.—The progress of the destruction and healing is usually slow and often progressive, and although the response to adequate treatment is good, tissue losses remain. Death may result from general exhaustion, sepsis, insufflation pneumonia, or other intercurrent disease.

Treatment.—Energetic anti-yaws therapy is indicated, and intercurrent disease may need treatment.

Juxta-Articular Nodes

Definitions.—Multiple, painless, fibrotic nodules occurring in the vicinity of joints and bony prominences in the later stages of yaws.

Ætiology.—This condition is probably found wherever yaws is prevalent, and has been reported from most tropical countries. It is rare in childhood and is characteristically seen in elderly people often together with chronic pre-patellar bursal enlargement. Similar lesions are occasionally met with in late syphilis and in bejel.

Pathology.—The nodules consist of hard, greyish-white, avascular fibrous tissue, in which may be opaque yellow spots and occasional areas of necrosis. Foci of chronic inflammatory cells are found microscopically; endarteritis is said not to occur but treponemata have been demonstrated in

them. The tumours have no capsules, and merge into the neighbouring connective tissue.

Symptoms.—The nodules appear as small round multiple tumours in the subcutaneous tissue about joints and bony prominences, especially the knee, elbow and over the femoral trochanter. Only a few are present at any one situation; they are painless, firm and even cartilaginous in consistency, and only rarely break down and ulcerate. They are usually freely movable under the skin, but later some attachment to the skin at the most prominent point may occur. Their development is slow, and the nodules may resolve spontaneously or remain stationary. Their usual size is 1 to 2 cm., but some may become much larger.

Diagnosis.—Differentiation from syphilitic, rheumatic and onchocerca nodules may be necessary. Biopsy may be of assistance. In onchocerciasis the tumours are often softer, and embryos may be demonstrated in aspirated fluid; on section they are loculated, and filariæ and embryos are present.

Prognosis.—The nodules may cause some discomfort at points of pressure, but do not endanger life.

Treatment.—If necessary, troublesome nodules may be excised. Intensive anti-yaws therapy may cause resolution in some and regression in others.

N. Hamilton Fairley.

LEPTOSPIROSIS

Since the causative organism, *Leptospira icterohæmorrhagiæ*, was first demonstrated in Japan by Inada and Ido in 1915, spirochætosis icterhæmorrhagica has been recognised in many different countries. The earliest observations indicating that strains of leptospira other than the classical spirochætosis icterohæmorrhagica strain might produce disease in man was made two years later in Japan when *L. hebdomadis* was shown by Ido, Ito and others to cause Japanese seven days' fever or Nanukayami disease. Subsequently several strains differing in antigenic structure were discovered in the Dutch East Indies and Malaya. In Europe swamp fever was recognised as a leptospirosis caused by *L. grippo-typhosus*, and in 1932 *L. canicola*, which commonly affects dogs, was shown to produce leptospirosis in man. More recently in Australia three new strains have been isolated. Schüffner has recently classified the leptospiras pathogenic to man on the basis of different antigenic structure as revealed by serological reactions and animal inoculations, the clinical picture, epidemiological considerations and geographical distribution. Nine different strains are recognised, and these are separated into two groups, *i.e.* those capable of producing jaundice and those which fail to do so, but it should be remembered that even in classical spirochætosis icterohæmorrhagica only 50 per cent. of patients develop jaundice. The clinical picture in leptospirosis caused by any of these strains include conjunctival congestion, fever, prostration, severe headache and generalised muscular pains; meningeal symptoms and rashes may also develop. A neutrophil leucocytosis is characteristic. The outstanding difference is in prognosis, for while many cases of classical spirochætosis icterohæmorrhagica die, patients infected with

other strains almost invariably recover. Early blood culture, inoculation of guinea-pigs with blood or urine, serum agglutination reactions and other serological tests are essential to establish the diagnosis of leptospirosis and determine the strain of leptospira implicated.

I. Leptospirosis associated with Jaundice

Four strains pathogenic to man are included in this group:

(1) The classical Weil strain, *L. icterohæmorrhagiæ*, is cosmopolitan in distribution and lethal to guinea-pigs. The natural reservoir is *Rattus decumanus*, and it is known that in many different countries rats of this species pass *L. icterohæmorrhagiæ* in large numbers in the urine; these organisms infect man through skin abrasions or via the nasal mucous membranes during submersion in contaminated water. Only rarely the disease is acquired from infected dogs and cats.

(2) Akiyami A strain is similar to *L. autumnalis* of Japan and the Rachmat strain of the Dutch East Indies. The natural host is *Apodemus speciosus* in Japan where it has an autumnal prevalence.

(3) The Salinem strain, or *L. pyrogenes*, of the Dutch East Indies is probably identical with the Zanoni strain, which is one of the two leptospiræ responsible for leptospirosis amongst the cane-cutters of Queensland, Australia, in the rainy season. It has been found in a local species of rat—*R. culmorum*. The strain is lethal to guinea-pigs.

(4) The Batavia strain is found only in Java where *R. decumanus* appears to be the reservoir host. It is less pathogenic for guinea-pigs than the other strains described above.

II. Leptospirosis without Jaundice

Five strains pathogenic to man are included in this group:

(1) *L. hebomadis* causes seven days' fever in Japan. It is primarily an infection of the field vole, *Microtus montebelli*, and appears in the urine, which contaminates soil or food. It has recently been found in Sumatra in dogs and man.

(2) *L. grippo-typhosus* gives rise to summer epidemics amongst field workers in Europe, but the reservoir host and mode of infection is unknown. The disease runs a benign course. It has also been isolated from patients with leptospirosis in the Andamans (Andaman B strain).

(3) *L. canicola* produces an epizootic in dogs, from which man acquires the disease by contact. The rat is not a reservoir host. In Canicola-fever, though jaundice is absent, the meningitic symptoms often appear more severe than in classical Weil's disease. In inoculated guinea-pigs its virulence is enhanced with passage.

(4) The Pomona strain produces fever lasting 3 to 8 days, and has been isolated from agricultural workers in Queensland. It occurs after rain.

(5) The Ballico strain causes leptospirosis in Queensland on the cane plantations after rain. It produces a mild fever lasting a week. It is lethal to guinea-pigs and has been found in local rats.

N. Hamilton Fairley.

SPIROCHÆTOSIS ICTEROHÆMORRHAGICA

Synonyms.—Spirochætal Jaundice; Weil's Disease.

Definition.—An acute febrile disease with a world-wide distribution, caused by *Leptospira icterohæmorrhagiæ*, and generally occurring in people with an occupational relationship to rats. In its typical severe form it is characterised by fever, profound prostration, headache, generalised pains and acute muscular tenderness, conjunctival hyperæmia, leucocytosis, albuminuria, jaundice, and a tendency to hæmorrhage. Subclinical infections may occur, and jaundice is absent in about 50 per cent. of cases.

Ætiology.—In 1886, Weil first directed attention to this disease, which is now associated with his name. In Japan it was well known amongst miners and labourers in the rice fields, and in 1914 Inada and Ido infected guinea-pigs with blood from human cases and demonstrated *L. icterohæmorrhagiæ* in the tissues. Later, rats (*Rattus decumanus*) were found to be the reservoir host; the leptospiras, which were localised in the kidney, escaped in the urine and often contaminated water, fungal slime and soil. In man infection generally occurs in people who work in rat-infested places, and follow occupations in which minor injuries and abrasions of the skin are common; this accounts for its incidence in sewer labourers, bargemen, canal and dock workers, fish and tripe cleaners, coal miners and farm labourers. In Great Britain the disease is recognised as an occupational one, for which compensation may be claimed under the Workmen's Compensation Act. In trench warfare troops may become infected. The disease may also be acquired via the nasal passages from infected water when bathing or during immersion accidents, which mode of infection is particularly common in Holland.

Pathology.—(1) Morbid Anatomy.—In fatal cases there is an acute hepatitis with jaundice, while parenchymatous degeneration of the tubular epithelium of the kidneys, perhaps associated with hæmorrhages into Bowman's capsules, is characteristic. Large and small hæmorrhages are often scattered throughout the tissues and particularly affect the stomach, intestinal mucosa, and the lungs.

(2) Isolation of the Leptospira.—*L. icterohæmorrhagiæ* may be isolated by blood culture on Fletcher's medium during the first week, or by injecting 5 c.c. of infected whole blood intraperitoneally into the guinea-pig up till the tenth day of the disease. In the cultures there is a time lag of 3 to 5 days before leptospiras are found, and of 5 to 8 days before they appear in the viscera or blood of inoculated guinea-pigs. Where meningeal symptoms develop leptospiras may be found in the cerebrospinal fluid, and they are often demonstrable in the urine after the second week.

(3) Serological Reactions.—The agglutination reaction, using formalised cultures as advised by Schüffner, yields satisfactory results. Agglutinin appears in low titre about the fifth or sixth day, and rapidly increases during the second and third week of the disease; maximal titres up to 1/4000 have been recorded. Agglutinins persist for many years after an attack, and multiple observations to determine an increase in titre may be necessary in cases in which the titre is low and residual agglutinin may have persisted from a previous infection. The adhesion test of Brown and Davis has also proved of definite value.

Symptoms and Course.—The incubation period varies from 6 to 12 days. In moderately severe cases presenting the classical clinical picture three stages are recognised: (1) a febrile stage, with sudden onset; (2) an icteric stage, associated with renal features, and sometimes hæmorrhage; and (3) a convalescent stage, in which febrile relapses are common.

(1) Febrile Stage.—This generally lasts 6 to 8 days. As a rule the onset is sudden, with shivery feelings and definite rigor. Headache, nausea, vomiting, profound asthenia, backache, photophobia, and generalised muscular pains are characteristic. So severe may the muscular pain and tenderness be that the patient cries out with agony on the slightest movement. Conjunctival injection is common and herpes with hæmorrhage into the vesicles not infrequent. The muscles of the limbs and the abdominal muscles are often exquisitely tender on palpation. There may be some enlargement of liver or spleen but often this is absent even in the icteric stage of the disease. A neutrophil leucocytosis is characteristic; the total count varies between 10,000 to 20,000 leucocytes per c.mm., and the neutrophils equal 80 to 85 per cent.

(2) Icteric Stage.—An icteric tinge of the conjunctivæ and lemon yellow tinting of the skin appear from the fourth to the sixth day, but is only found in about 50 per cent. of cases. The jaundice gradually deepens and may become a deep orange in colour. A direct biphasic van den Bergh reaction develops, with well-marked hyperbilirubinæmia; in a recent series one patient whose plasma contained 56 units recovered, and another with a maximum value of 29 units died of cholæmia. With the onset of jaundice the urine becomes dark brown, and contains bile salts and bile pigments. The stools contain excess of fat, which is adequately or excessively split, and are often pale brown or even white in colour, the result of a decrease of stercobilin.

Evidence of renal involvement is not infrequent and the urine, which is decreased in quantity, contains albumin, renal casts, pus cells and perhaps red blood corpuscles. As renal function fails the nitrogenous constituents of the blood increase and the blood urea attains high values. Anuria may ensue. Hiccough, Cheyne-Stokes respiration, subsultus tendinum, delirium and coma are features common to cholæmia and uræmia, which are frequent causes of death. Skin petechiæ or purpuric patches sometimes appear and bleeding gums, hæmoptysis, hæmatemesis, melæna and hæmaturia may complicate the picture.

(3) Convalescence.—This generally commences in the third or fourth week, by which time the renal and hepatic manifestations have subsided, but it is often 5 or 6 weeks before the patient is fit to leave hospital. Not infrequently in the third week a relapse of fever occurs, which may last from a few days to 3 weeks; it is unaccompanied by icterus or other severe symptoms.

Atypical Clinical Types: These are frequent, and may or may not be associated with jaundice. They include:

(*a*) *Anginal type.*—The patient complains of fever, generalised pains and sore throat, and is usually diagnosed as influenza, tonsillitis or rheumatic fever. Unless jaundice develops or the occupation of the patient suggests the possibility of spirochætosis icterohæmorrhagica, laboratory

investigations are not made and the true nature of the infection remains unrecognised.

(*b*) *Abdominal type.*—There is fever, abdominal pain, vomiting and localised or generalised rigidity associated with acute tenderness of the abdominal muscles; the picture may resemble an acute abdominal condition, such as appendicitis, cholecystitis, pancreatitis or peritonitis. A neutrophil leucocytosis is present, and when hæmatemesis occurs, perforated gastric ulcer may be diagnosed.

(*c*) *Respiratory type.*—There are physical signs of pulmonary consolidation resembling pneumonia, and hæmoptysis may supervene. Jaundice may never develop.

(*d*) *Meningeal type.*—Not uncommonly leptospiral meningitis, with neck retraction, Kernig's sign, etc. may develop at the onset. Lumbar puncture reveals a clear fluid under increased pressure, containing neutrophil leucocytes, lymphocytes and perhaps monocytes, while leptospiras may be demonstrated by animal inoculation or culture. More rarely, chronic meningitis may supervene months after the acute stage of the disease has subsided, but notwithstanding this the cerebrospinal fluid contains pus cells and leptospiras.

Subclinical infections also occur in which people like sewer workers acquire a symptomless leptospirosis; there is no history of illness yet the blood shows definite agglutination against *L. icterohæmorrhagiæ*.

Diagnosis.—Few diseases are more protean in their clinical manifestations or have remained for such long periods undetected in communities. Spirochætosis icterohæmorrhagica is not generally suspected until the patient develops jaundice and there is known to have been an occupational relationship to rats or a recent water-immersion accident. An appeal to the laboratory under such circumstances will generally enable a delayed diagnosis to be made, either by isolating the leptospira or by serological tests. Apart from jaundice, a history of possible contact with rat-infected material, the extreme prostration, the conjunctival injection and the severity of the muscular pain and tenderness, and the neutrophil leucocytosis, should arouse suspicion.

Prognosis.—Fatal cases are almost invariably jaundiced and die between the ninth or fourteenth day as a rule from cholæmia or uræmia. The mortality rate appears to vary in different outbreaks, but where the diagnosis is reasonably good it is about 15 per cent.

Treatment.—PROPHYLACTIC.—This includes the protection of bathing pools, abattoirs, fish shops, etc., from rats, and the immediate treatment and protection of any skin abrasions in people whose occupation brings them in contact with rat-infected material. Prophylactic vaccination is under trial. Nurses should be instructed to disinfect the patient's urine.

CURATIVE.—Chemotherapy has proved disappointing and intravenous injections of anti-leptospiral serum in large dosage at the earliest possible moment is the only specific treatment holding out any prospect of success. Owing to the hepatitis and renal involvement, the protein content of the diet should be minimal and fluids and dextrose given in large quantities. Intravenous dextrose (5 per cent.) and citrates are of special value.

W. H. WILLCOX.
N. HAMILTON FAIRLEY.

RELAPSING FEVER

Synonyms.—Spirochætosis; Febris Recurrens; Spirillum Fever; Famine Fever.

Definition.—A group of specific infectious fevers due to spirochætes (treponemata) and spread by lice or argasine ticks, characterised by a variable number of febrile relapses.

Ætiology.—Relapsing fever occurs in many parts of the world and is often seen in epidemic form during wars and famines. It is rare in England, but occurs in parts of Europe, including Russia, and in Turkey, India, Cochin-China, Algiers, Egypt, Africa and the United States it is not infrequent. All ages and both sexes are liable. The different varieties of the disease are caused by spirochætes demonstrable in the peripheral blood during the febrile paroxysms, and they may be divided into the lice-borne and tick-borne fevers. The varieties transmitted by lice include (1) European relapsing fever due to *Treponema recurrentis* (the old spirillum of Obermeier); (2) Northern African relapsing fever produced by *T. berberum*; (3) Indian or Asiatic relapsing fever caused by *T. carteri*; (4) North American relapsing fever attributed to *T. novyi*. The varieties transmitted by the argasine ticks include (1) Central African tick fever due to *T. duttoni* transmitted by *Ornithodorus moubata, O. erraticus* and *O. savignyi*; (2) Palestinian tick fever caused by *T. sogdianum* and transmitted by *O. papillipes*; (3) Persian and North-West Indian relapsing fever caused by *T. persicum* and transmitted by *O. papillipes* (*tholozani*) or *O. lahorensis*; (4) Spanish relapsing fever attributed to *T. hispanicum* and transmitted by *O. maroccanus*; (5) Central and South American relapsing fever due to *T. venezuelense* is transmitted by *O. venezuelensis* in Columbia and Venezuela, and by *O. talaje* in Panama; (6) Californian tick fever due to *T. turicatæ* and transmitted by *O. hermsi*. At present it appears somewhat doubtful whether the creation of the numerous species of spirochætes detailed above is justified on grounds other than those of convenience. Lice become infective about the sixteenth day, and remain so for about one month. Infection is probably conveyed by the fæces, or after the louse has been crushed and the spirochætes liberated from the codomic fluid; scratching may play an important part in transmission. With ticks the spirochætes are liberated in the coxal fluid, and the anal excrement is also said to be infected; from this source man generally acquires the disease, but it is also possible that it may be transmitted during biting, as spirochætes are demonstrable in the salivary glands of ticks. The ova become infected and new generations of ticks can pass on the disease in hereditary fashion.

Pathology.—In uncomplicated cases petechial hæmorrhages and occasionally jaundice are found. The spleen is soft and congested and often the site of multiple infarcts, while the liver is enlarged, friable and hyperæmic, and along with the kidneys and heart shows cloudy swelling and fatty degeneration. The long bones contain red marrow. Congestive changes in the cord and brain and iritis have also been described, especially with *T. duttoni*. Microscopically, spirochætes are demonstrable in endothelial cells throughout the body, especially in the liver and spleen, and also in the

brain and cerebrospinal fluid. Monkeys are susceptible and, as in the case of rats and mice, are actively immune after recovery. Krantz has applied the Reichenberg reaction or "adhesion test" to relapsing fever spirochætes, specific immune serum causing the spirochætes and blood platelets to adhere together.

Symptoms.—A. The Lice-borne Relapsing Fevers.

1. *European form.*—The incubation period varies from 2 to 12 days, and in accidental inoculations it is about 5 to 7 days. During this period slight prodromata may occur. The onset is sudden with a rigor, frontal headache and intense pains in the back and limbs. Anorexia, nausea and vomiting are common, and in children convulsions may occur; the temperature and pulse rise rapidly, the former often reaching 104° F. on the evening of the first day. The tongue is coated and moist, the spleen is enlarged, and in some epidemics jaundice and a tender enlarged liver may be present. Herpes labialis may develop, and occasionally an erythematous rash appears at onset. Later, rose-coloured spots may involve the skin of the neck, trunk and inner aspect of the thighs. Petechiæ are observed only in severe cases. After the fever has persisted for 5 to 7 days the temperature falls by crisis, accompanied by profuse sweating and possibly diarrhœa and collapse. The patient rapidly improves, but after an apyrexial period a relapse ensues, generally about the fourteenth day, followed by a second crisis about the end of the third week (twenty-first day). This usually terminates the illness, but occasionally a third relapse is noted. Spirochætes are present in the blood until 24 hours before the crisis, when they rapidly disappear, and are not demonstrable except possibly in thick smears during the apyrexial period when a leucopenia replaces the characteristic febrile neutrophile leucocytosis. The blood remains infective between relapses, and if injected into a mouse or white rat spirochætes appear in 24 hours.

2. *Asiatic relapsing fever* closely resembles the European form, but rigors are not so common, collapse is more frequent at the crisis, and relapses more numerous. Carter describes two varieties: (*a*) a short irregular remittent fever; (*b*) the so-called bilious remittent or icteric fever. This is a severe form of infection associated with spirochætal hepatitis. There is high fever, intense toxic jaundice, skin petechiæ, splenomegaly, and an enlarged tender liver. The urine contains albumin, bile pigments, bile salts and urobilin. There is hyperbilirubinæmia associated with a direct biphasic Van den Bergh reaction in the plasma. Toxæmic features are marked, and include a dry brown tongue, diarrhœa, abdominal distension, hiccough, stupor, delirium and coma. Death not infrequently results.

3. *North African relapsing fever* is found in Algiers, Tunis and Egypt, and closely resembles the European form. The number of relapses rarely exceeds three, but fatal cases may show jaundice, bilious vomiting, hepatomegaly, splenomegaly with infarctions, and albuminuria, necessitating differentiation from yellow fever.

4. *American relapsing fever* due to *T. novyi* has a low mortality rate and not generally more than one relapse.

B. The Tick-borne Relapsing Fevers.

1. *Central African relapsing fever.*—**Synonyms.**—Tick Fever; Tete Disease; Carapata Fever.

This form is found throughout British and Portuguese East Africa, Nyasaland, Uganda and the Congo Free State.

It differs from the European form in the shorter duration of the initial fever (3 days), the irregular incidence, greater number of relapses and the scantiness of spirochætes in the peripheral blood. The incubation period varies from 3 to 10 days, generally being about 1 week. The tick bites may be accompanied by local inflammatory changes and the prodromata include mental lethargy and sweating. The attack may start gradually with malaise, vomiting and slight temperature which gradually increases, or suddenly with dizziness, headache, and generalised pains, the temperature rapidly reaching 104° F. After the pyrexia is established these symptoms may persist and, in addition, chilliness, pain over the spleen, bilious vomiting, bronchial catarrh, diarrhœa, enlargement of the spleen and liver, albuminuria and herpes may occur. Generally after 3 to 4 days the fever terminates by crisis with profuse sweating. The patient feels weak and tired, but slowly regains his appetite and strength until the next febrile paroxysm, which may occur after an interval of 3 to 8 days. Third and fourth relapses are frequent and as many as ten may occur, weakness and emaciation then being marked. In severe and fulminating cases epistaxis, hæmaturia and jaundice may be met with, also occasionally involvement of the central nervous system, with coma and death due to cerebral embolism caused by tangled masses of spirochætes. Cranial nerve pareses are described, and spirochætes may be present in the cerebro-spinal fluid, which may show increased pressure and lymphocytosis.

2. *Persian and North-West Indian relapsing fever* presents a primary fever of some 4 days' duration followed by short bouts of pyrexial recurrence; five or more relapses are not uncommon. Some epidemics are very mild, others more severe. Often the spleen is not palpable, and icterus is uncommon except in the more severe epidemics.

3. Spanish relapsing fever caused by *T. hispanicum* resembles the tick fever of Central Africa. The initial fever lasts about 4 days, and is associated with splenomegaly and neutrophil leucocytosis. Iritis and facial neuritis are not infrequent complications during relapses, which do not generally exceed four in number.

Complications and Sequelæ.—Bronchial catarrh is not infrequent during the initial fever, and pneumonia and parotitis may also occur. In some epidemics hæmatemesis and hæmaturia have been noted; in others jaundice and hepatomegaly are not infrequent. Rupture of the enlarged spleen has been reported, also ophthalmia, adenitis, neuritis and diarrhœa. In *T. duttoni* infection conjunctivitis, iritis and cranial nerve palsies coming on in the late relapses may be encountered. Optic atrophy has also been described.

Diagnosis.—Relapsing fever has to be distinguished from influenza, typhus, malaria and trypanosomiasis, and, if there is jaundice, from yellow fever and Weil's disease. This is done by finding the specific parasite in the blood.

Prognosis.—The prognosis varies. With the European types the mortality rate is only 3 to 5 per cent., but with the Asiatic type it is much higher. Jaundice is an unfavourable development. African tick fever is not infrequently fatal, especially in the aged and debilitated, and Central American tick fevers resemble the Central African variety.

Treatment.—PROPHYLACTIC.—Avoidance of contact with lice and ticks is necessary if infection is to be prevented. Delousing of troops in war-time is important. With *O. moubata* the avoidance of native dung huts, especially at night-time, and of old camping sites, is essential.

CURATIVE.—Good nursing is important and strict dieting necessary especially where there is icterus and hepatomegaly. Arsphenamine (0·3 to 0·6 g.) and neoarsphenamine (0·6 to 0·9 g.) are specifics in all types of the disease, and generally not more than two injections are needed for cure: resistant strains, however, do occur in which much more intensive treatment is necessary. The injections should be given during the pyrexial period, and preferably when spirochætes are demonstrable in blood smears and not immediately before the crisis. This is especially so in resistant cases of the Central African type for which combined treatment with Solganal B and neoarsphenamine may prove necessary. Collapse at the crisis may require stimulants like digitalis, pituitary (posterior lobe) extract and strychnine. If the nervous symptoms be severe, lumbar puncture may be advisable to reduce intracranial pressure.

RAT-BITE FEVER

Synonyms.—Sodoku; Sokoshio; Rat-bite Disease.

Definition.—A chronic relapsing type of fever following the bite of rats, and due to the *Spirillum minus* (Carter, 1887); it is characterised clinically by a return of the inflammation in the healed wound, lymphangitis, adenitis, rigors, fever and a macular or papular purplish rash.

Ætiology.—The disease is common in Japan, China and Bombay, and cases have been reported from France, Italy, Spain, Britain, East Africa, West Indies and Australia. Any one bitten by an infected rat may acquire the disease. In man the spironemata were found in the bitten tissues and in the lymph glands by Futaki; they are demonstrable with difficulty in the peripheral blood, appearing as thick, short forms (3 to 6 microns), which on cultivation increase in length (20 microns). About 3 per cent. of house rats in Japan are carriers, and after experimental inoculation spirilla are present in the blood for the first fortnight of infection.

Pathology.—In human cases, degenerative changes in the liver and kidneys have been reported, while animals show congestion and swelling of the lymph glands and spleen.

Symptoms.—After being bitten the wound heals up in an ordinary manner, but in from 2 to 6 weeks pain and swelling appears at the site of the old bite and the scar breaks down. The lymphatics draining the area of the bite become inflamed, with enlargement of the corresponding glands; a definite ulcer may now mark the site of the bite, with an angry inflammation spreading away from it, and small vesicles may break out around it. When this has continued for some time, general symptoms make their appearance; the temperature rises to 103° F. or over; there may be rigors, vomiting, nausea, severe headache, joint pains, diarrhœa and general malaise. A specific rash then usually appears as dusky-coloured, purplish red spots, or a coloured, patchy erythema over the limbs, trunk and face, which lasts for some time and slowly disappears. After remaining high for 3 to 8 days, the temperature drops, often by crisis, and the symptoms generally ameliorate. After a

varying period of time the first relapse appears with a return of the former symptoms. Pyrexia then disappears, only to be followed by further relapses, which in some of the reported cases have continued for months or even years. Considerable debility follows the attacks, and finally the patient may pass into a very poor state of health. A transient or permanent nephritis may result, and exophthalmos and paresis have been seen in some cases. Ultimately the infection tends slowly to disappear.

Diagnosis.—The history of rat-bite, the local lesion associated with lymphangitis and adenitis, the specific rash, and recurrent fever are typical. In some ways the disease resembles syphilis, but the Wassermann reaction is negative. Spirilla are difficult to demonstrate in the peripheral blood, and white rats or mice should be inoculated with human blood.

Prognosis.—With modern treatment this is quite good, but previously it was not so, many cases continuing with chronic symptoms for years. A mortality of 10 per cent. has been given by some authors.

Treatment.—Arsphenamine or some of its derivatives should be given, commencing with doses of 0·3 gram. One or two injections are usually sufficient to abolish completely all the symptoms and bring about a permanent cure.

G. Carmichael Low.
N. Hamilton Fairley.

E. PROTOZOAN INFECTIONS

MALARIA

Synonyms.—Ague; Paludism; Remittent, Intermittent, Marsh or Jungle Fever.

Definition.—A protozoal disease of man caused by various species of *Plasmodium* which infect the red corpuscles and give rise to periodic fever, splenomegaly and anæmia; transmission is by anopheline mosquitoes.

Historical.—Malarial fevers were recognised by Hippocrates in the fifth century B.C., while in the time of Cæsar, Varro suggested they might originate from swamps. In the Middle Ages, Europe suffered severely from the ague, being saved from its ravages by Cinchona bark brought back from Peru by the Jesuits in the first half of the seventeenth century, and not by the Countess del Chinchon, as is generally believed; this remedy also enabled Sydenham and other physicians to separate malaria from other fevers. Laveran (1880) discovered both the parasite and the phenomenon of flagellation in shed blood, but differentiation into the three species was not made until later. Manson (1894) formulated the hypothesis of mosquito transmission, inducing it from the phenomenon of flagellation of the male gamete, but he thought man acquired the disease from infected mosquitoes via water and not by biting. McCallum (1897) recognised the fertilising function of the "flagellating body." Ross (1898) worked out the correct transmission and developmental cycle of bird malaria (Proteosoma) in culicine mosquitoes, and having previously observed the partially developed oöcysts of human malaria in dappled winged mosquitoes (anophelines) he predicted a human life cycle

similar to that observed in bird malaria. Later in the same year, Grassi, Bignami, and Bastianelli (1898) observed the complete development of malignant tertian malaria in *Anopheles maculipennis* and transmitted the disease to man by the bite of infected mosquitoes.

Ætiology.—Malignant or subtertian malaria greatly preponderates in tropical and benign tertian in temperate zones, while in the subtropics all three forms may occur. Quartan has a patchy distribution. Some islands, such as Fiji, are free of malaria. All races are susceptible, and in endemic areas the infection is commonest in children. An infected population gradually acquires a certain degree of immunity, and in avian and simian malaria this has recently been shown by Taliaferro and others to depend on an enhanced phagocytic function and hypertrophy of the reticulo-endothelium, especially of the spleen and liver. In Europe the disease disappears at 3000 feet, and in India and Africa at 6000 feet. Seasonal prevalence, which is not marked near the equator becomes so farther from it. Malignant tertian malaria is responsible for most fatal epidemics, which are generally associated with excessive rainfall. The great Ceylon epidemic of 1934–1935 was an exception, for the benign tertian parasite played an important rôle and it was associated with failure of the South-West Monsoon. Drought conditions followed, and in water holes caused by drying up of the rivers and lakes the mosquito vector, *Anopheles culicifacies*, bred in great numbers. Famine conditions due to failure of the crops further lowered individual resistance, and within 7 months 80,000 people died from malaria.

The parasites of malaria belong to the *Sporozoa*, sub-order *Hæmosporidia*, genus *Plasmodium*. Four forms affect man—benign tertian (B.T.) due to *Plasmodium vivax* (Grassi and Feletti, 1890), a tertian malaria due to *Plasmodium ovale* (Stephens, 1922), quartan malaria due to *P. malariæ* (Laveran, 1881), and malignant or subtertian malaria (M.T.) due to *P. falciparum* (Welch, 1897) (*Laverania malariæ* or *præcox*). The parasites undergo two cycles, one in man, the other in the mosquito.

Human phase (endogenous, asexual or schizogony). The sporozoites, inoculated by the mosquito, pass into the blood stream and enter the red cells where they change into little rings which gradually develop more protoplasm and black pigment. Quartan fills the corpuscule, while benign tertian actually expands it. The pigment collects centrally, and the protoplasm and chromatin divide into spores (sporulating body, rosette or schizont). The envelope bursts and the spores (merozoites) are scattered in the plasma whence they penetrate new corpuscles restarting the cycle.

Mosquito phase (exogenous, sexual or sporogony). When the sporulation of the asexual cycle takes place in benign infections certain large non-sporulating sexual forms (gametocytes) fill the corpuscles. Malignant tertian gametes are crescentic, and when taken up by suitable mosquitoes revert to circular bodies. Subsequent development is as follows: from the male gamete flagella become detached which penetrate the female bodies and fertilise them (sexual act, zygosis). The resulting body now elongates (travelling vermicule or oökinet), penetrates into the stomach wall, where it again takes on a circular form, developing into oöcysts which, after becoming filled with numerous spindle-shaped bodies (sporozoites), protrude like little herniæ or warts. Finally these rupture and the sporozoites escape into the body cavity and thence into the salivary glands. The infected mosquito inoculates man

with the saliva during biting, and the sporozoites, passing into the corpuscles, start the infection. (See Human phase.) At suitable temperatures, development in the mosquito takes about 10 days, and following human inoculation by the mosquito there is an incubation period of from 9 to 21 days or longer, varying with the species of parasite.

Cases of *Plasmodium ovale* infection (Stephens, 1922), have been reported from South, East and West Africa and Venezuela. Though morphologically it resembles *P. malariæ*, the infected corpuscles show Schüffner's dots, and are often oval or distorted in shape, with serrated edges; the schizogonous cycle takes 48 hours and tertian fever is produced. After experimental infection of man, either by direct inoculation with infected blood (Yorke), or following bites from artificially infected mosquitoes (James), the parasite preserves its morphological characters in blood smears.

Mosquito Vectors of Malaria.—It is not every anopheline mosquito which can transmit malaria successfully. Perhaps the best-known transmitter of malaria is *A. maculipennis*, which is nocturnal in habit, and has been specially studied in Europe and the Eastern Mediterranean. The recent work of Hackett, Misseroli and others have shown that *A. maculipennis* is not a uniform species but is divided into "biological races" or varieties. These races cannot generally be distinguished either as adult or larvæ, but only by their egg characteristics. The breeding grounds, sexual behaviour and feeding habits differ. Thus, the race called *elutus* bites man for choice, and is a dangerous carrier of malaria; other races, like *typicus* and *messeæ*, bite cattle for choice, and therefore are much less dangerous to man. The larva of *elutus* needs traces of salt in water, and for this reason it tends to have a coastal distribution. In the Balkans, malaria of the plains is mainly transmitted by *A. maculipennis* var. *elutus*, whereas malaria of the hills is solely transmitted by *A. superpictus*, which especially breeds in running mountain streams with rough rocky beds. *Anopheles sergenti* occurs in Syria and Palestine, and breeds in water which is still or running slowly. *A. bifurcatus*, which occurs in Europe and has generally little relationship to malaria, used to be a common source of this disease in Palestine; it bred in underground cisterns, inside towns and villages, and produced much urban malaria. *A. culicifacies*, which causes malaria in Ceylon, breeds in the dry season in trickles of water and water holes in the empty beds of rivers. It follows that the mosquito vector must be carefully studied in every country and special local methods devised for its extermination. Other mosquito vectors in other parts of the world include: *A. funestus* and *A. costalis* in Africa; *A. albimanus* and *A. argyrotarsis* in the West Indies; *A. culicifacies*, *A. turkhudi* and *A. maculipalpis* in India; *A. umbrosus*, *A. maculatus* and *A. minimus* in Assam, Burma and the Federated Malay States. Mosquitoes are not liable to develop infection unless the carrier has more than 12 gametocytes per c.mm. (Darling), and development of the malarial oöcyst in the mosquito's stomach is temporarily inhibited by low temperatures.

Parasites in blood smears.—All forms of benign tertian and quartan parasites are met with in the peripheral blood, but in malignant tertian malaria, owing to sporulation in the internal organs, generally only the small rings and the large crescents appear. Smears are stained by Leishman's or Giemsa's stain, and the following points assist in differentiating the different

species. *Ring forms.*—The rings of *P. falciparum* occupy about one-sixth of the cell, which may show Maurer's spots; they are often fine and hair-like and show irregular or flattened marginal forms: two chromatin dots and multiple infection of the same corpuscle may occur. Occasionally this is seen with *P. vivax*. The rings of *P. vivax* and *P. malariæ* occupy about one-third of the cell, are larger and contain more cytoplasm, but often the species cannot be determined if only ring forms are present (Wenyon). *Partly grown forms.*—In *P. vivax* the infected corpuscle is enlarged, Schüffner's dots are often present, and the parasites are of irregular shape and contain light brown pigment. With *P. malariæ* there is no enlargement of the corpuscle, the pigment is dark brown or black, band forms are common, and Ziemann's stippling may be demonstrated in the red cells by special staining. *Adult forms.*—In *P. vivax* and *P. malariæ* the schizonts have 16 and 8 nuclei or merozoites respectively, in contrast with which the gametocytes have a single nucleus and a different distribution of pigment and chromatin.

Pathology.—*Clinical.*—In severe infections, especially with M.T. parasites, there is considerable blood destruction. The intracorpuscular parasite probably uses hæmoglobin as a pabulum and produces brownish black malarial pigment, which is a hæmatin compound of unknown composition found in the parasites, the parasitised corpuscles and in the R.E. cells of the liver, spleen, serous membranes and marrow. The hæmatogenous bilirubin may attain a concentration of 3·0–6·0 units, and is responsible for the hæmatogenous jaundice observed clinically. The hæmatogenous bilirubin is converted by the liver cells into bile pigment, and pleocholia ensues with dark coloured stools containing an excess of stercobilin which on re-absorption produces urobilinuria, especially if there is an associated malarial hepatitis. The malarial anæmia in uncomplicated cases is generally normocytic in type, and in severe infections the blood picture may show anisocytosis, poikilocytosis, polychromasia, punctate basophilia, and occasionally normoblasts. Though there is no demonstrable hæmoglobinæmia, Schumm's test for methæmalbumin is generally positive in febrile malaria, indicating that lysis of corpuscles is occurring during the paroxysms.

Morbid anatomy.—In a fatal case of acute malignant tertian malaria the spleen need not necessarily be much enlarged; it is blackish red in colour, with a soft, diffluent pulp. The liver is congested and plum-coloured, the lungs darkish red and œdematous, and the peritoneum and intestinal mucosa leaden in colour. The heart may be dilated, and the brain may show œdema, congestion, punctate hæmorrhages, and a distinct leaden hue. Microscopic study shows malarial pigment in the hypertrophied reticulo-endothelial cells of the liver, spleen, serous membranes and bone marrow, and sometimes pigmented mononuclears in the vessels. The liver, kidneys and heart muscle may show parenchymatous degeneration, and hæmosiderin giving a Prussian blue reaction is found in the hepatic, renal and splenic cells. The internal capillaries of the brain, and often of the viscera and serous membranes as well, may be packed with parasites, and local anoxæmia and degenerative changes ensue. In more chronic cases the spleen is very enlarged, hard, and slaty grey in colour; the capsule is thickened, and there is generally perisplenitis. Sometimes the adhesions are calcified. On section, Malpighian bodies are not in evidence. Microscopic section shows great hypertrophy of the R.E. cells, which often contain malarial pigment, atrophy of the

Malpighian bodies and lymphoid tissue generally, and an increase in fibrous tissue.

Death in benign tertian malaria, quartan malaria and chronic malignant tertian malaria is generally associated with malnutrition and anæmia, with congestive heart failure or intercurrent disease, such as pneumonia, ancylostomiasis or dysentery.

Symptoms.—The benign varieties, *i.e.* those generally unassociated with fatal symptoms, include both benign tertian and quartan fevers, whereas pernicious manifestations are restricted to malignant tertian malaria. The initial pyrexia may be continuous, remittent or quotidian in type, and only later does the characteristic intermittent periodic fever, commencing in the forenoon or early afternoon, become established.

Quartan.—The classical features of ague are present with cold, hot and sweating stages, the rise of temperature being caused by the escape of merozoites into the circulation. Headache, pains in the limbs and joints, backache, fatigue and malaise, followed by chilly sensations, often initiate the rigor; violent shivering and chattering of the teeth follow and the face is pinched and blue. As the chill passes off, blankets are discarded, the face flushes, and nausea, vomiting, severe headache and even delirium may ensue. The skin remains hot and dry until the sweating stage with its fall in temperature brings relief. The whole paroxysm generally lasts only 4 to 5 hours. Temperatures of 105° F. to 106° F. are not uncommon. Single quartan infections give rise to fever every fourth day, *i.e.* 72 hours' interval; double infections will cause 2 days' fever and 1 clear, while treble infections induce daily pyrexia. The spleen is moderately enlarged and tender, and considerable secondary anæmia may develop, often associated with albuminuria. Quartan malaria is rarely fatal, but, like benign and malignant tertian malaria, it predisposes to intercurrent infections like tuberculosis and pneumonia. It may persist as long as 8 years if untreated.

Benign tertian.—The clinical picture is very similar to that described for quartan malaria, but the paroxysm lasts 8 to 12 hours. A single infection causes fever every third day with 48 hours' interval between the paroxysms, while a double infection gives rise to quotidian fever. Herpes is common, and in addition to splenomegaly the liver is sometimes increased in size. The natural course of the untreated disease does not exceed 2 to 3 years.

Malignant tertian malaria.—**Synonyms.**—Subtertian, Æstivo-autumnal or Pernicious Malaria. The Italians have described two quotidian and one tertian variety, but quotidian fever is due to a double cycle, just as continuous or remittent fever is attributable to several generations at slightly different times; such charts show small pyrexial peaks corresponding to the successive generations of parasites. Recently James has shown that the different strains of malignant tertian vary considerably in their virulence and response to treatment. Three types of fever are seen: (1) A typical tertian temperature; (2) Quotidian fever; (3) Continuous irregular or remittent fever resembling enteric. In malignant tertian the initial rise of temperature is abrupt; chilliness may be present, but there is no rigor (dumb chill), the hot stage is considerably prolonged, and the sweating stage is not marked. The paroxysms may last some 12 to 20 hours, but frequently the fever never intermits, remaining remittent in type. Headache, backache, nausea, vomiting and anæmia tend to be more severe than in the

benign forms, and as fever becomes more chronic ague-cake spleen and malarial cachexia ensue. Severe hæmolytic anæmia may develop within the first few weeks. The gravest cases, clinically somewhat resembling pernicious anæmia, may show dyspnœa, palpitation, hæmic murmurs, retinal hæmorrhage, hyperbilirubinæmia and urobilinuria; the counts in extreme instances reach 1 to 2 million erythrocytes per c.mm., but the colour index does not exceed 1·0, megalocytosis is not evident, nor is the average diameter of the corpuscle greater than normal (7·6 microns).

Bilious remittent fever.—Two types are encountered: one is characterised by splenomegaly, hæmolytic jaundice, bilious vomiting and perhaps bilious diarrhœa, associated with hyperbilirubinæmia, pleocholia and mild urobilinuria; the immediate direct van den Bergh reaction is negative, and bile pigments and salts are absent from the urine. The other has similar clinical features, but in addition there is a tender enlargement of the liver, epigastric distress and sometimes gastro-intestinal and other hæmorrhages: the jaundice comes on early and a biphasic van den Bergh reaction may be found. Urobilinuria is marked, and there are often bile pigment and salts in the urine. In the latter type degeneration and necrosis of the polygonal cells of the liver occur, and a toxic factor is superadded to the jaundice of hæmolytic origin characteristic of the milder type.

Blackwater fever.—This complication of subtertian malaria is dealt with separately.

Forms of pernicious malaria.—Apart from the hæmolytic effects of parasites on the red cells and their destruction within reticulo-endothelial cells, internal sporulation and clumping of corpuscles causing plugging of the visceral capillaries in the brain, lung, liver, heart, intestines, spleen and bone marrow may give rise to a variety of pernicious manifestations, which may simulate almost any disease in medicine. For clinical purposes they may be classified as follows: (1) *Cerebral.*—Cases may show coma, convulsions, aphasia, paraplegia, hemiplegia, meningismus and perhaps hyperpyrexia. (2) *Spinal.*—Clinical syndromes simulating spinal meningitis may also be encountered. (3) *Abdominal.*—Choleraic and dysenteric types may develop, also intestinal hæmorrhage. In the peritoneal type appendicitis or acute pancreatitis may be diagnosed, and the patient erroneously operated on. (4) *Cardiac.*—Syncope associated with a dilated right heart and various forms of disordered cardiac action may develop. (5) *Respiratory.*—Mild bronchitis and broncho-pneumonia relieved by quinine are reported. (6) *Sudoral.*—Here excessive sweating results in collapse and syncope. (7) *Hyperpyrexial.*—The clinical picture simulates that of heat stroke, and is often classified under cerebral malaria.

Complications and Sequelæ.—Malarial cirrhosis of the liver does not occur, but the tendency to the formation of soft pigment stones in the gall bladder appears to be increased. Twisting of the pedicle or rupture of the spleen from slight trauma may be encountered. Lack of mental concentration, amnesia and certain psychoses may follow cerebral malaria. Neuralgia, neuritis, corneal ulceration, iritis, retinal hæmorrhages, optic neuritis and orchitis occasionally occur. Herpes labialis is common, especially in benign infections. Hepatitis with jaundice may occur, and nephritis with œdema is not infrequent in quartan malaria. In pregnancy, abortion often results unless the fever is stopped by giving atebrin, quinine or other specifics.

Diagnosis.—Special points of clinical importance are splenomegaly, secondary hæmolytic anæmia, periodic fever commencing in the forenoon or early afternoon, and the therapeutic response to quinine. In the apyrexial phase a leucopenia and monocytosis of over 15 per cent., especially if associated with urobilinuria, are highly suggestive of malaria, while the demonstration of parasites completes the diagnosis. Blood smears should, when possible, be made before quinine is administered, and the examination of thick films may be of considerable diagnostic value where parasites are scanty in the peripheral blood.

Prognosis.—Malaria is the chief cause of death in the tropics, being specially serious amongst young children and in those suffering from intercurrent disease like dysentery and ancylostomiasis, as well as in undernourished or famine populations, and those on deficient diets. Furthermore, the debility and leucopenia induced by malaria render the individual more susceptible to incurrent infections like broncho-pneumonia and sepsis. In benign forms the prognosis is generally good as regards life, but cases may relapse repeatedly even after intensive and prolonged quinine treatment; in the Ceylon epidemic, however, especially in cases in which pregnancy or ancylostomiasis co-existed, death not infrequently resulted. In malignant forms the death-rate will be proportionate to the skill of the clinician in diagnosing his cases: speedy recognition of the complaint means early treatment and saving of life. In the absence of treatment, pernicious forms generally die, and intravenous quinine is essential in cerebral malaria or where there is much vomiting.

Treatment.—PROPHYLACTIC.—Destruction of adult vectors, anopheline larvæ and their breeding-grounds by drainage, etc., and the application of oil or spraying with Paris green should be carried out. Tropical residents should obliterate potential breeding-places in their bungalows and gardens, sleep under mosquito nets and, where possible, live in mosquito-proof houses. After sunset mosquito boots and the application of oil of citronella to the wrists and neck may be useful. Prophylactic quinine, grains v. daily, though it does not prevent infection, prolongs the incubation period and tends to keep the infection subclinical. Pamaquin (plasmoquine), on account of its lethal action on gametocytes, may prove more valuable.

CURATIVE.—The drugs which are of specific value in malaria are quinine, pamaquin and mepacrine hydrochloride (atebrin). Arsenic compounds have a distinct therapeutic action on *P. vivax*, but exert little effect on *P. falciparum*. Bed rest is essential during the febrile period and is advisable for several days after cessation of fever. Constipation must be avoided, and sodium sulphate or similar aperients should be administered regularly. Aspirin during the paroxysm is useful, and iron in full dosage assists in blood regeneration.

Quinine.—This remains the sheet anchor of malarial therapy and generally should be given by the mouth. In the acute attack quinine is most potent in benign tertian, less active in quartan, and least so in malignant tertian malaria. Regarding cure of relapses, it has less effect on *P. vivax* and *P. malariæ* than on *P. falciparum*, in which the relapse rate is considerably less than in benign tertian malaria. Quinine acts effectively on the subtertian schizonts and allays acute symptoms, but does not affect the development of either the gametocytes or the sporozoites. Various salts are available,

ine + Pulv. Rhei Co helps to disguise the bitter taste. (Dr Haq)

including the bihydrochloride, hydrochloride, bisulphate, sulphate, euquinine and tannate. Opinions vary regarding the optimum dosage and duration of treatment, and James suggests that a delay in quinine administration may be advisable in non-urgent cases until natural antibodies have developed. Regarding dosage, some advocate 30 grains daily for 1 month; others give 10 grains thrice daily for 1 week and thereafter 5 grains night and morning for 2 to 3 weeks. The dosage should certainly not be less than 15 grains daily for 10 days. Owing to its solubility the bihydrochloride should be used for both intramuscular and intravenous injections, the dosage being 7½–10 grains in 10 c.c. of distilled water. Quinine by the mouth may be given in solution or cachets, but not in pills made with insoluble salts as they may fail to dissolve and not be absorbed. Children bear quinine well, the dosage being appropriate to the age. In malarial patients its administration is advisable in the puerperium and before operation or anæsthesia (10 grains daily). Intramuscular injections of concentrated quinine may cause necrosis of muscle and sterile chemical abscess may result; bacterial abscesses, tetanus and gas gangrene have also been reported following injection with contaminated material. Intravenous injections are much preferable provided the solution is adequately diluted and injected slowly; it can be employed (1) where vomiting is excessive; (2) where quinine is ineffective *per os*; (3) where absorption of quinine is defective as shown by its absence from the urine when tested with Mayer-Tanret's reagent; (4) in such pernicious manifestations as cerebral and algid malaria where speed is essential to save life. Occasionally in the tropics malarial fever proves refractory even to intravenous quinine, and similar findings have been recently recorded by James, with certain strains in experimentally induced malaria. The toxic effects of the drug include tinnitus, visual and gastric disturbances, deafness and amblyopia: idiosyncrasy may result in severe erythematous and urticarial rashes. Cinchona febrifuge, consisting of the combined alkaloids of cinchona, is advocated by Acton on economic grounds; the dosage is 21 grains daily for 10 days.

Mepacrine hydrochloride (*quinacrine, atebrin*), a synthetic acridine derivative which, like quinine, acts on the asexual parasites within the corpuscles, but has little action on the gametocytes and none on the sporozoites. It is given in tablet form in doses of 0·1 g. thrice daily after food for 5 to 7 days, and this course can be repeated once or twice after a week's interval. It is at least as effective as quinine in ridding the blood of parasites, relieving symptoms and preventing relapses. Headache, abdominal discomfort, intestinal colic and a transient yellow staining of the skin may result from its administration; troublesome dreams, mental disturbances and certain psychoses have been recorded as occasionally associated with its administration. When doubt exists as to whether atebrin is being absorbed from the intestine, its excretion in the urine should be tested by adding sulphuric acid; in the presence of atebrin an intense yellow colour is produced and the solution gives a marked fluorescence with ultraviolet light.

If the drug is not being absorbed, or in cases of urgency, a soluble preparation—atebrin musonate—can be injected intramuscularly. It is available in ampoules containing a dosage equivalent to 0·1 g. or 0·3 g. atebrin. Local pain and toxic cerebral features were recorded following its use in the Ceylon

epidemic. Mepacrine hydrochloride should be given in preference to quinine in pregnancy and in patients who have previously had blackwater fever; in the latter the urine should be rendered alkaline with citrates.

Pamaquin (prœquinine, plasmoquine)—a synthetic quinoline derivative—was shown by Rochl to destroy malignant tertian gametocytes, but to have practically no effect on schizonts, whereas in benign tertian and quartan infections it probably acts on both phases of the parasite; sporozoites are also affected, but too large a dose has to be employed prophylactically to prevent infection entirely. It is put up in tablets—plasmoquine simplex—containing 0·01 g. and 0·02 g., one tablet being given thrice daily after food for 5 days. Toxic symptoms include headache, abdominal pain, cardiac arrhythmia, cyanosis and methæmoglobincythæmia, the methæmoglobin being found within the corpuscle and not free in the plasma.

Combined Treatment.—Pamaquin (0·01 g.) can with benefit be given with quinine (0·125 g.) in the form of pamaquin-compound, two tablets being taken twice daily after food for 7 days. It is advised to repeat such a course of treatment four times with a four-day interval between each course. Pamaquin used to be given simultaneously with mepacrine hydrochloride, but owing to the frequency of abdominal pain and other toxic complications, it is now customary to give a course of mepacrine hydrochloride (0·1 g., t.d.s., p.c.) for 7 days and after an interval of 3 days to give a course of pamaquin (0·01 g., t.d.s., p.c.) for 5 days. The same treatment can be repeated after an interval of 7 days. This combination of mepacrine hydrochloride followed by pamaquin gives excellent results and has much to recommend it.

Another synthetic drug—certuna—with strong gametocidal action has recently been described by Kikuth, and as its toxicity is less marked than pamaquin and it can be given along with mepacrine hydrochloride, it may possibly replace pamaquin in malaria therapy.

Patients with latent malaria must be specially warned against getting wet, bathing, excessive exertion and alcoholism, as these factors precipitate relapses.

BLACKWATER FEVER

Synonyms.—Hæmoglobinuric or Melanuric Fever; Malarial Hæmoglobinuria.

Definition.—An acute complication of chronic malignant tertian malaria, characterised by one or more intravascular hæmolyses of considerable severity, hæmoglobinuria, fever, vomiting, jaundice and anæmia.

Ætiology.—Blackwater fever occurs in Nyasaland, Uganda, the Sudan, East Africa, West Coast Colonies and other parts of tropical Africa, in the Duars, the Terai and the Jeypore Hill tract (Madras) in India, in Italy, Greece, Macedonia and Palestine, in the southern states of the U.S.A., Panama, etc. It invariably originates in an endemic zone heavily infected with malignant tertian malaria. Native populations may enjoy immunity, while colonists, imported natives and even visitors are attacked. Its most

frequent incidence occurs from 1 to 5 years' residence, but it may appear within 3 months. Multiple attacks are common. Though seen more frequently in males, both sexes and children as well as adults are susceptible. Practically every case gives a history of chronic malaria, often associated with irregular quinine intake, the rare exceptions being examples of latent infection. Quinine is the great factor precipitating the attack, but chill and over-exertion sometimes do so as well. Pamaquin (plasmoquine) also may precipitate blackwater, but mepacrine hydrochloride (atebrin) infrequently does so. Some have regarded the condition as due to a biological lysin, others suggest it may have an anaphylactic origin or be caused by a direct hæmolytic action of quinine on the corpuscle. There is no evidence of dermal hypersensitivity or of idiosyncrasy to quinine, and no lysin has been demonstrated. Possibly the intracellular lysin normally contained in R.E. cells which have hypertrophied as a result of chronic malaria, is suddenly liberated into the blood. Such lysin may become immediately fixed to the corpuscles in the visceral vessels and so be no longer demonstrable in the peripheral blood.

Pathology.—*Morbid anatomy.*—The skin is jaundiced, the blood watery, the serum sometimes tinged with hæmoglobin, while malarial pigment may persist in the viscera although not in large amounts. The liver is enlarged and soft, the bile thick and tarry, the spleen big and its pulp almost diffluent; the kidneys are dark, swollen and intensely congested. Microscopically, hæmosiderin is found in the liver and spleen in which malarial pigment may also be evident. Eosinophilic, granular debris blocks the tubules of the kidney, and there is toxic degeneration and desquamation of the cells of the convoluted tubules. Cloudy swelling and necrosis of liver cells, especially of the centre of the lobule, may occur generally associated with malarial pigment in Kupffer's cells.

Clinical pathology.—Malarial parasites, often present in blood smears at the beginning of the attack, are rare after 24 hours, and generally absent at autopsy. The urine shows albumin, oxy-hæmoglobin and urobilin in excess; methæmoglobin is generally demonstrable. Bile is present only in the most severe cases, and ketones may also appear. The characteristic sediment consists of brown, granular debris and granular casts. Red blood corpuscles are scanty or absent. The plasma contains oxyhæmoglobin, and after some hours methæmalbumin as well. There is an intense hyperbilirubinæmia with an indirect van den Bergh reaction of 5 to 85 units, but immediate direct reactions only occur in the severest cases with toxic changes in the liver. The blood urea is markedly raised, the excess being derived partly from destroyed corpuscles and partly from renal retention; one case in our series which recovered showed a blood urea of 450 mg. per 100 c.c. When only a limited number of nephrons are blocked, urea retention leads to polyuria; where blockage is extensive oliguria or even anuria results. In the latter type of case renal acidosis may develop; this is associated with lowering of the CO_2 combining power of the plasma, a decrease in serum calcium, and an increase in the blood phosphorus. Anæmia is frequently profound, and in severe cases 50 per cent. of the corpuscles may be destroyed overnight. A study of the excretion curves of urinary hæmoglobin shows that several distinct intravascular hæmolyses may occur.

Results of Hæmoglobin Disintegration.—In malaria red cells are destroyed

during sporulation when malaria pigment and some undestroyed hæmoglobin gains access to the blood stream. Many of the parasitised corpuscles, however, are phagocytosed by the hypertrophied reticulo-endothelial system, where they undergo intracellular lysis, with the production of bilirubin and hæmosiderin. In blackwater fever the circulating corpuscles are destroyed *in situ*, and frank hæmoglobinæmia results; also hæmoglobinuria whenever the concentration of the extracorpuscular hæmoglobin exceeds the renal threshold. If the reaction of the urine be acid the oxyhæmoglobin tends to be converted into methæmoglobin and acid hæmatin which is precipitated along with granular debris, causing a variable degree of blockage of the tubules. Some of the circulating hæmoglobin is absorbed directly by the reticulo-endothelial cells, with the production of hæmosiderin and bilirubin. The resulting hyperbilirubinæmia accounts both for the hæmolytic jaundice and the pleocholia, with bilious vomiting and dark brown stools; while the absorption of surplus stercobilinogen causes urobilinuria, especially in the presence of liver damage. Finally, any residual circulating hæmoglobin is split into globin and reduced hæmatin (ferrous), which is immediately oxidised to oxyhæmatin (ferric) and unites with serum albumin to form methæmalbumin (Fairley, 1938). It is this pigment which in the past has been confused with methæmoglobin, but which differs from it in its extra-corpuscular distribution, and in having an α band at 623 $\mu\mu$ which is not altered by Stokes's reagent, but is dispersed by strong ammonium sulphide with the production of a hæmochromogen having an α band at 558 $\mu\mu$.

Symptoms.—No recognisable pre-blackwater fever stage exists, and the patient generally thinks an ordinary attack of malaria is impending. The onset is generally sudden, with chill and loin pain, but in mild cases red or black urine may be the first indication. A rise of temperature is almost invariable, rigor is common, and nausea, bilious vomiting and epigastric discomfort are characteristic. The urine, which may be pinkish or red at first, soon becomes port-wine or porter-coloured, presenting the characteristics described. As the condition progresses polyuria, oliguria or anuria may develop. Within a few hours yellowish discoloration of the skin and conjunctivæ is apparent; this increases in intensity as hæmoglobinuria continues, but only in the severest cases is bile found in the urine. The pulse is rapid and of low tension at first, and the blood pressure in severe cases is markedly depressed (S/D = 80/50) at onset, though later it rises. Hiccough is a serious feature and there may be great restlessness, anxiety, pallor, cold extremities, and thready pulse occasioned by the rapidly developing anæmia. As many as 2,000,000 red cells per c.mm. may be destroyed in 24 hours by recurrent hæmolyses. Headache and lumbar pain are characteristic. The spleen and liver are generally demonstrably enlarged and tender, and may cause discomfort; the spleen decreases in size during the attack. Localised tenderness over the distended gall bladder may also occur. The fever at onset resembles a malarial paroxysm, is highest at first, becomes intermittent or remittent later, and generally declines in 3 to 4 days as the vomiting subsides and the urine clears. Post-hæmoglobinuric fever may appear after hæmoglobinuria has ceased and persist well into convalescence. Hyperpyrexia may develop especially in the late phases of the disease, while some cases show a marked tendency to hæmorrhages in

the skin and the gastro-intestinal tract. In one of our series the rash simulated that of typhus fever.

Several different clinical types are encountered: (1) Mild hæmoglobinuria, especially common in children, in which blood pigment in the urine is only found for a few hours. (2) Severe hæmoglobinuria, associated with the clinical features already described. These are separated into two groups: (*a*) the polyuric type in which renal excretion is well maintained despite evidences of nitrogenous retention, and (*b*) the oliguric and anuric types. Catheterisation at first shows small quantities of highly albuminous, perhaps bile-stained, urine, followed later by complete suppression. Anuria may set in early, and is associated with a normal or subnormal temperature. Hepatogenous jaundice not infrequently develops. Life may be prolonged for many days, and death occur without signs of uræmia.

Toxæmic features are common in both these types. Their differentiation is important, since blood transfusion is a life-saving procedure in polyuric cases. (3) Intermittent hæmoglobinuria, in which blood pigment is present in the urine from time to time, though in the intervals it disappears entirely. In these cases the temperature continues and post-hæmoglobinuric fever is common; icterus and anæmia are well marked.

Course and Complications.—Complications include anuria, post-hæmoglobinuric fever, anæmia, retinal hæmorrhages, biliary colic, pigment calculi and cholecystitis. About 10 per cent. of cases relapse during the course of an attack (Ross). Convalescence may be prolonged owing to anæmia and transient renal dysfunction, but there is no evidence that chronic nephritis results.

Prognosis.—The prognosis depends to a considerable extent on the quantity of corpuscles destroyed, and if during any single rapid hæmolysis this amounts to half a litre of normal blood, and the reaction of the urine be acid, a fatal anuria appears inevitable. The mortality rate varies from 20 to 40 per cent., and though some cases are doomed from the onset, in others modern therapy favourably influences the course of the illness. Unfavourable features include rapidly increasing jaundice, grave anæmia, severe hiccough, anuria and hyperpyrexia, while bile in the urine or a persistent increase in the blood urea and bilirubin is a grave prognostic omen.

Treatment.—Prophylactic.—The prophylaxis of blackwater fever is that of malaria. Where there is a previous history of hæmoglobinuria, the urine should be alkalinised with citrates and atebrin given in preference to quinine for febrile malaria.

Curative.—The causes of death in blackwater fever are well known, and in the absence of knowledge concerning the mechanism of the hæmolysis and of specific remedies for terminating it, the therapeutic indications are: (1) to combat the anæmia, anoxæmia and heart failure; (2) to alkalinise the urine, to prevent or relieve suppression, and to decrease the toxæmia. Measures directed to these ends include absolute rest in bed in the recumbent posture, fluid by various routes, oral and intravenous citrates, intravenous glucose and blood transfusion. Transport is justifiable only if it places the patient under better conditions for treatment. Careful nursing is all important. The diet at first should consist of bland fluids like barley water, fruit juices and glucose; later, milk, fruit jellies, junket, custard

and Benger's food are allowed. Proteins are restricted well into convalescence owing to renal involvement. Fluids are pushed *per os* and should contain sufficient sodium bicarbonate and potassium citrate to alkalinise the urine, and so lessen the clogging of the renal tubules. Should vomiting prove troublesome gastric lavage may be practised and water, alkalis and glucose given per rectum. In all cases where the urine is acid in reaction 1 pint of bicarbonate of soda solution (150 grains to 1 pint) should immediately be injected intravenously and repeated if necessary; the solution must be sterilised by filtration or by adding the bicarbonate to cooled boiled water, since actual boiling is liable to convert it into the toxic carbonate. Recent work by Busby, Hart, Kekwick and Whitby on alkalinisation of the urine indicates that 150 c.c. of a 3 per cent. solution of sodium citrate (4·5 g. = gr. eq.) is sufficient to render the urine temporarily alkaline; alternatively, 8 g. of potassium citrate given *per os* has the same effect. To keep the *p*H of the urine on the alkaline side of 7·0, 35 g. potassium citrate should be given together with 3000 c.c. of fluid in the 24 hours. Lemon juice, coffee or milk disguise its disagreeable flavour. Alternatively, a total of 600 c.c. of 3 per cent. sodium citrate (18 g.) in 2400 c.c. of 5 per cent. glucose by intravenous drip may be administered every 24 hours. The onset of alkalosis is suggested by headache, giddiness, vomiting and muscular cramp. As a clinical index to *p*H, the urine may be regarded as sufficiently alkaline if it turns red litmus blue, or if the urine is a bright red indicating unchanged hæmoglobin. When the urine has a brownish tint, or is porter-coloured, methæmoglobin is present and the urine requires alkalinisation. Intravenous injections of dextrose assist the heart's action and help to combat toxæmia and urinary suppression. One to 2 pints of a 5 per cent. solution are used, but in anuria a 10 to 20 per cent. solution is a more potent diuretic; hot fomentations to the loins, dry cupping and colonic douches with hot saline (120° F.) are all useful for this purpose. Diuretics like caffeine citrate and caffeine sodium benzoate have their advocates, and the bowels should be kept opened with salines or calomel. In collapsed cases with low blood pressure, warmth, pituitary extract and elevation of the foot of the bed may be of benefit. Transfusion is the best means of dealing with anæmia, and in severe cases manifesting rapid blood destruction and cardiac weakness 1 pint of citrated blood from a suitable donor should be given without delay even during the hæmolytic period and repeated if necessary. In polyuric cases blood transfusion is a life-saving procedure, but its effect in the anuric type of case is more uncertain, for though it may improve the blood count, death from uræmia may still ensue. Once the hæmolysis has stopped marked reticulocytosis, followed by blood restoration, generally proceeds automatically in the well-fed European, but iron in adequate dosage and liver injections are beneficial in vegetarians and in people living on diets deficient in good animal protein; in addition, blood transfusion may be advisable under such circumstances. Regarding specific therapy opinions differ. The tendency of the hæmolysis is to destroy the great mass of the parasites and occasionally natural cure results. Where parasites persist in the blood a course of mepacrine hydrochloride should be given; otherwise treatment with anti-malarial drugs is better postponed until convalescence.

LEISHMANIASIS

Leishmaniasis is the term applied to a group of diseases caused by parasites of the genus Leishmania. Some of these are general infections, others are local. Of the first, we have kala-azar, due to *Leishmania donovani* (Laveran and Mesnil, 1903) and infantile or Mediterranean kala-azar caused by *L. infantum* (Nicolle, 1908). Both morphologically and serologically they are the same parasite, no marked differences occur in inoculated animals, and there seems no reason to separate them. Oriental sore, due to *L. tropica* (Wright, 1903), and American dermal leishmaniasis, due to *L. braziliensis* (Vianna, 1911), are, however, distinct species belonging to the second group, and according to Noguchi are separable serologically.

Kala-azar

Definition.—Kala-azar, or black fever, is a specific disease associated with enlargement of the spleen and liver, anæmia, great emaciation and irregular fever of long duration caused by the protozoon *L. donovani*, present in the peripheral blood and reticulo-endothelial cell system.

Ætiology.—The disease has definite geographical limitations, being commonest in India, Assam and the Mediterranean littoral, where 90 per cent. of the cases occur in children ; it is also found in China, Indo-China, the Sudan, Abyssinia, Russian Turkestan and Mesopotamia. Natives appear more susceptible than Europeans, probably owing to different habits of life. In Assam villages the introduction of an infected case generally precedes other cases, and often it appears to be a house infection (Rogers). Children and young adults are specially liable, and males appear more susceptible than females.

The rounded non-flagellate stage of the parasite is a small oval body, 2 to 5 μ long by 1 to 2 μ broad, containing two structures, one a large round laterally placed nucleus (macronucleus or trophonucleus) staining bright red with Romanowsky's stain, the other (kinetoplast, micronucleus, centrosome), which is usually rod-shaped, stains a deep reddish-purple and has one end pointing toward the nucleus. It can be cultivated on rabbit-blood agar (N.N.N. medium) if grown for 2 to 3 weeks at room temperature (22–25° C.), provided the culture material has not been contaminated (Rogers). During growth Leishmania bodies develop into leptomonads measuring up to 24 microns in length, with a flagellum and centrosome at one end and a central macronucleus. This flagellate undoubtedly represents an intermediate stage in some insect vector which is almost certainly the sand-fly. In India it was Sinton's original observation that the local distribution of *Phlebotomus argentipes* coincided with that of kala-azar, which led to the transmission experiments of Knowles, Napier and Smith. It is now known that if sand-flies be fed on kala-azar cases, heavy leptomonas infections develop in the mid-gut, œsophagus and pharynx, these parasites being capable of producing the disease if artificially injected into hamsters. Infection, however, has only once been successfully transmitted by the actual biting of infected sand-flies. In the Mediterranean area very young children and dogs suffer from kala-azar, whereas in India

and North China infections occur mainly in older people and extremely rarely in dogs. Adler suggests that the former infections result from biting, the latter from crushing these insects.

Pathology.—The parasites are very generally distributed in the endothelial cells of the capillaries throughout the body, where they multiply, eventually burst through, and are subsequently taken up by phagocyte cells of the blood and tissues. Common sites for the parasite are the reticulo-endothelial cells of the liver, spleen, lymphatic glands and bone-marrow; less commonly they occur in the lungs, pancreas, kidneys, adrenals, testicles, intestinal submucosa, intestinal ulcers and the lymphatics draining them (Manson and Low). The central nervous system is never involved. Meleney holds that the macrophage or reticulo-endothelial cells respond specifically by local multiplication in this disease, forming "clasmatocytic tissue." At autopsy emaciation is marked, the spleen and liver are generally enlarged, while dropsical effusions and intestinal ulceration may occur. The spleen is at first soft, pulpy and friable, later it becomes hard and fibrous; the capsule is thickened, and perisplenitis and infarcts may also be present. The liver is firm and friable, the capsule is thickened, and fatty degeneration and a nutmeg appearance are common; cirrhosis may eventually result. The bone-marrow is generally red and soft, showing a decrease of fat, while the mesenteric glands are often enlarged, presenting a central necrosis. The heart is dilated and flabby, while the entero-colon may show superficial or deep ulcerations. Napier holds that the latter at least are of dysenteric origin. Post-kala-azar dermal leishmaniasis has recently been described.

Symptoms.—The incubation period is probably from 1 to 4 months, but cases may occur 1½ years after exposure. The onset, especially in endemic areas, may be sudden, with fever simulating malaria or typhoid, or it may be insidious. Often in febrile cases the diagnosis is not made until relapses occur and the more classical features of the disease develop. These may be classified as follows: (1) Irregular remittent or intermittent pyrexia which, though not necessarily high, is characteristic. Periods of apyrexia spontaneously develop, especially during the day, and may lead to confusion with Malta fever. A double daily rise may occur in the afternoons and evenings (20 per cent. of cases), but this may also be noted in other diseases and is not pathognomonic. (2) Loss of hair and deepening colour or pigmentation of the skin—hence the name black fever. (3) Anæmia with the characteristic blood changes. (4) Rapid loss of weight and cachexia. (5) Splenomegaly, which may be the first sign or only be noted after 1 to 2 months of fever. In the early stages the spleen feels soft and doughy, but not tender; later it hardens and may reach very large dimensions. (6) The liver is generally palpable (88 per cent.), presenting a sharp lower edge. (7) Diarrhœa.—There is good appetite associated with poor digestion which itself may lead to intermittent diarrhœa (Napier). If blood and mucus be present, intercurrent dysentery should be suspected. (8) Other features include night sweats, persistent irritating cough, palpitation, dyspnœa, low blood pressure, *i.e.* below 100 mm. of mercury, œdema of the extremities and occasionally puffiness of the face. Amenorrhœa often develops, but conception may occur with congenital transmission from the mother (Low and Cooke). The blood changes, which include anæmia, leucopenia and reduction in the platelet count, are due to replace-

ment of both the leucoblastic and erythroblastic marrow by clasmatocytic tissue. The hæmoglobin is often proportionally reduced, so that the colour index may equal 1·0; in other cases it is 0·7 or 0·8. The blood picture may show anisocytosis, poikilocytosis, polychromasia and normoblasts. The leucopenia is extreme, often sinking to 2000 per c.mm., and in 80 per cent. of cases it is less than 4000 per c.mm. The differential count reveals a relative increase in lymphocytes and monocytes, with a decrease in neutrophiles and eosinophiles. The coagulability of the blood may be prolonged, the calcium, blood sugar and serum albumin are reduced, and the total globulin content of the blood is raised, euglobulin increasing at the expense of the pseudo-globulin fraction.

Complications and Sequelæ.—Owing to debility and bone-marrow involvement with leucopenia, the resistance to bacterial infections is markedly decreased, and influenza, broncho-pneumonia, lobar pneumonia and tuberculosis are common causes of death; otitis media and cancrum oris may occur, especially in children. Watery diarrhœa is common and intercurrent dysentery frequent. Purpura, epistaxis, bleeding from the gums and melæna may be encountered. The sequelæ include chronic splenomegaly plus severe anæmia and cirrhosis of the liver, sometimes associated with ascites and demonstrable parasites. Jaundice frequently appears within 3 months of treatment and may persist for several months. Post-kala-azar dermal leishmaniasis has recently been described. Areas of depigmentation generally appear about a year after antimony injections, and papillomatous nodules, in which leishmania can be found, occur the following year. A xanthoma-like condition is also described, but ulceration never occurs. Parasites are demonstrable in smears and culture, and apparently they are confined to the skin as splenic puncture yields negative results. Occasionally the condition appears in persons who give no history of previous kala-azar or of treatment.

Course.—Bentley showed in the Assam epidemics, prior to the introduction of antimony, that the disease lasted 1 to 2 years in chronic cases. The mortality rate, if untreated, is about 90 per cent.

Diagnosis.—Kala-azar has to be differentiated from the febrile splenomegalies of the tropics, especially chronic malaria, undulant fever and enteric fever; schistosomiasis, Banti's disease and leukæmia must also be considered, and owing to the danger of hæmorrhage in the latter disease splenic puncture should never be undertaken until blood examination has excluded it. In childhood Mediterranean kala-azar has to be differentiated from Cooley's anæmia, commonly found in Greece, von Jaksch's anæmia and acholuric jaundice. Diagnosis is generally dependent on the demonstration of *L. donovani* in smears from the liver or spleen or cultures on N.N.N. medium obtained from the peripheral blood. Parasites are less common in the peripheral blood in Mediterranean than in Indian kala-azar. Aspirated material for microscopical examination must be collected in an absolutely dry syringe.

The formol-gel or aldehyde test of Napier is of considerable value in the diagnosis of kala-azar, especially when the result is positive and associated with a leucopenia. The test is performed by adding 1 drop of commercial formalin (30 per cent. formaldehyde) to 1 c.c. of clear serum, which is immediately shaken and left at room temperature. When the reaction is positive

the serum immediately becomes viscid, and within 1 or 2 minutes assumes a whitish opalescent appearance and sets so that the tube can be inverted without spilling. In from 3 to 20 minutes it forms a solid opaque coagulum like the white of a hard-boiled egg.

For the first three months the reaction is of doubtful value, but after this it is generally positive.

Prognosis.—Intercurrent disease, severe intestinal symptoms, and cirrhosis with ascites are of grave significance. Modern therapy generally results in recovery, provided the condition is not too advanced and intercurrent disease absent.

Treatment.—PROPHYLACTIC.—Segregation and treatment of the sick, and abandonment of infected houses and rebuilding at distances not less than 300 yards have been effective in India. Destruction of the probable sand-fly vector and of its breeding-places is indicated.

CURATIVE.—The patient is put to bed on a milk or light diet and intercurrent disease treated. Napier advocates an iron tonic mixture, and tincture of digitalis if there is cardiac weakness. Certain antimony compounds are specific, the most difficult form to cure being Mediterranean kala-azar. At first the trivalent compounds of the tartar-emetic type were employed, but now pentavalent antimony derivatives, such as neostibosan, are replacing them, owing to their rapid action, reduced toxicity for the host and increased toxicity for the parasite. *Trivalent antimony compounds.*—Antimony and potassium tartrate, and antimony and sodium tartrate are given intravenously on an empty stomach in a 2 per cent. solution thrice weekly. The initial dose is ½ grain, increasing by ½ grain until a maximum of 2 to 2½ grains is attained. Only freshly prepared solutions sterilised by boiling should be employed, and the total course is 40 to 60 grains. Effects of treatment are to reduce the temperature to normal, decrease the splenomegaly and hepatomegaly, increase body weight and restore the leucocytes to normal numbers. Cough and nausea following injections are not important, and rheumatic-like pains are frequent. Sever toxic manifestations like bradycardia, severe vomiting, diarrhœa and jaundice necessitate a suspension of treatment. Numerous other trivalent compounds have been employed, including antimosan, which is less toxic than tartar emetic, but almost as slow in producing cure. *Pentavalent antimony compounds.*—These include stibamine, von Heyden 693 or neostibosan, stibenyl, urea-stibamine, aminostiburea, neostam, urea-stibol and stibosan von Heyden 471. The dose of urea-stibamine, amino-stiburea and neostam as advocated by Napier is 0·1 g. initially, 0·2 g. as a second dose and 0·25 g. for each subsequent injection. With stibosan and von Heyden 693 (neostibosan) an initial dose of 0·2 g. with subsequent doses of 0·3 g. is advisable. Debilitated patients require smaller doses, while children, although tolerating proportionally larger doses than adults, receive smaller initial doses. The length of different courses varies from 8 to 15 daily injections. Toxic features include vomiting, giddiness, nausea, and more rarely diarrhœa, hepatitis and jaundice and an alarming anaphylaxis-like syndrome, producing puffiness of the face, urticaria and cardio-vascular collapse, etc. The beneficial effects of treatment are similar to those described with the trivalent compounds, except that the drugs act quicker and more effectively. Cure is indicated by an absence of clinical symptoms for 6 months, a negative aldehyde test, an increase in serum albumin associated

with a decrease in total globulin involving the euglobulin fraction, and a permanent disappearance of parasites.

Oriental Sore

Synonyms.—Tropical Sore; Aleppo Sore; Bagdad Boil; Delhi Boil; Biskra Button; Bouton d'Orient; Date Boil, etc.

Definition.—An infective granuloma of the skin and subjacent tissues caused by *Leishmania tropica*, producing nodular lesions which generally break down and form chronic indolent ulcers.

Ætiology.—The condition is common in parts of the East, including Mesopotamia, Arabia, Persia, Asia Minor and the North-West Frontier of India. It also occurs in Northern Africa, Egypt, the Sudan, Nigeria, the French Congo, and has been reported in Spain, Italy and Greece. Essentially it is a disease of towns, notably of Bagdad, Delhi and Lahore, and its incidence on exposed parts suggests an insect vector. Wherever it occurs sand-flies are common, and the remarkable development into virulent flagellates occurring in the mid-gut and extending forward to the proboscis after feeding them on oriental sores, indicates that these insects are the transmitters—probably *Phlebotomus papatasii* and *P. sergenti*. The parasite itself is morphologically indistinguishable from that of kala-azar and can be directly transmitted by inoculation; it is auto-inoculable, but not through the unbroken skin. Dogs, cats, guinea-pigs, etc., are susceptible.

Pathology.—Infective granulomata are produced, sections showing atrophy of the epidermis, infiltration of the corium and its papillæ with lymphocytes, plasma cells and macrophage endothelial cells containing *L. tropica*. If the nodule ulcerates secondary bacterial infection ensues. The keloid type of lesion described in the Sudan may show epithelial cell nests. Unlike the American form, the mucous membranes are rarely involved.

Symptoms.—The incubation period varies from 1 week to 6 months. Commencing as a small itching red papule, it develops into a nodule or blind boil, which occasionally persists for a year or more before disappearing. More usually the lesion becomes covered with a yellow crust and ulcerates, the ulcer having well-defined rounded edges and a granulation tissue base exuding thin pus. The sores may be single or multiple, as many as 35 having been recorded, and are specially common over the hands, wrists, feet, legs and face. Various other forms of dermal leishmaniasis due to *L. tropica* may be encountered. They include (1) small, firm, discrete nodules occurring in the course of the lymphatics; (2) warty outgrowths or papules known as the verrucose form, first described by Ferguson and Richards in Egypt; and (3) lupus-like nodules, which may implicate the cheek.

Diagnosis.—This is dependent on demonstrating the parasite. If ulceration has occurred the skin at the edge of the ulcer should be sterilised with iodine, punctured with a glass pipette, and the material so obtained inoculated on to N.N.N. medium. Bacterial contamination prevents growth. Direct microscopical examination of this material often shows *L. tropica* in the endothelial cells.

Prognosis.—The condition is practically never fatal even when untreated, but under these circumstances it may last 18 months, after which the patient generally possesses an immunity to further infection.

Treatment.—PROPHYLACTIC.—Sand-flies and their breeding-grounds should be eradicated.

CURATIVE.—In cases which have been secondarily infected, hot boracic fomentations or eusol dressings should be applied until sepsis is controlled and the crusts separate. Local treatment, like carbon dioxide snow, for 5 to 30 seconds every 10 days, X-ray, radium, zinc ionisation and diathermy are advocated as well as local applications of ointments containing methylene-blue, iodoform, salicylic acid and tartar emetic (1 to 2 per cent.): the latter may cause painful sloughing. Excellent results may be obtained with orisol ointment containing berberine sulphate and dianthrone (derobin, cignolin) paint, applied with a camel hair brush and strictly confined to the ulcer surface by covering it with paraffin wax. Vaccines have their advocates. Tartar emetic intravenously as given in kala-azar is the standard treatment, a total course of 20 to 30 grains being required. Neostibosan is also being used successfully, and is undoubtedly the most hopeful treatment when multiple lesions are present.

AMERICAN DERMAL LEISHMANIASIS

Synonyms.—Espundia; Uta; Pian Bois; Pian Cayenne; Forest Yaws; Bosch Yaws; Bubas Braziliana.

Definition.—An infective granuloma due to *Leishmania braziliensis*, producing cutaneous nodules and ulcers on exposed surfaces; the buccal and nasal mucous membranes may be extensively involved, also the lymph glands and lymphatics.

Ætiology.—It is found in South America, in Brazil, Venezuela, British and Dutch Guiana, Bolivia, Peru and Paraguay. The disease is specially frequent amongst wood-cutters and people living in forests: some wood-loving insect, tick or bug is thought to be the transmitting agent. Morphologically, *L. braziliensis* is similar to *L. tropica*, but differs serologically (Noguchi).

Symptoms.—The incubation period is about 2 months. The lesion originates as an itching papule, which may develop into a blind nodule or ulcerate, producing fungoid granulations. Later, ulcers appear at the margins of the mouth and nose, often subsequently involving their mucous surfaces, the larynx and nasal septum (20 per cent.). Fever, joint pains and bronchitic symptoms now appear, but many years may elapse before the patient succumbs to intercurrent disease.

Diagnosis.—Demonstration of the parasites either in scrapings from the spreading margin of the ulcer or by culture completes the diagnosis. Syphilis, rodent ulcer, leprosy and tuberculosis closely resemble the destructive form of *L. braziliensis* which, however, never involves bone.

Prognosis.—Untreated cases are liable to die of intercurrent disease or cachexia, but with tartar emetic treatment the prognosis is satisfactory.

Treatment.—Cases with extensive involvement of mucous membranes die if untreated, but even these recover with modern therapy, which is similar to that outlined for oriental sore and kala-azar. A full course of 30 or 40 grains of tartar emetic should be administered intravenously.

Stibophen (fouadin), a trivalent antimony compound, yields very satisfactory results: twenty to thirty intramuscular injections are given in a

graded dosage of from 1–5 c.c. Local treatment for ulcers on the lips and nose should also be instituted.

TRYPANOSOMIASIS

A group of diseases caused by flagellate parasites of the genus *Trypanosoma*. In Africa, man may be infected with *T. gambiense* or *T. rhodesiense*, and in South America with *T. cruzi*. Trypanosomes also produce disease in animals, the most important being nagana affecting horses, dogs, cattle and wild game in Africa caused by *T. brucei*, which is probably identical with *T. rhodesiense*. *T. evansi* produces surra and *T. equiperdum* dourine, the latter disease, like syphilis, being transmitted during coitus.

African Trypanosomiasis of Man

Synonym.—Sleeping sickness.

Definition.—This disease, transmitted by the bite of tsetse flies, is caused by *T. gambiense* (Dutton, 1902) or *T. rhodesiense* (Stephens and Fantham, 1910). After initial invasion by trypanosomes, blood infection ensues with adenitis, irregular remittent fever, rapid pulse, œdema and circinate erythematous rashes; later a meningo-encephalitis results with lethargy, mental and physical degeneration, tremors, shuffling gait, convulsions, coma and death. Mild cases, with headache and slight fever, are common.

Ætiology.—The disease is limited geographically to areas where the tsetse fly abounds and occurs in Western and Central Equatorial Africa, including the Congo, Uganda, East Africa, Rhodesia, Nyasaland, etc. Natives and whites are both affected, and children and adults of both sexes prove equally susceptible. The two species of trypanosome are indistinguishable in human blood; they possess a nucleus, a posteriorly situated blepharoplast and a flagellum. *T. rhodesiense* is identified by inoculating blood into white rats, when posterior nuclear forms develop; this so rarely occurs with *T. gambiense* that the test is one of real value in distinguishing these two trypanosomes. Furthermore, *T. gambiense* manifests an uncertain pathogenicity to laboratory animals, and is relatively insusceptible to the action of normal human serum. Glossinæ take up trypanosomes from the blood during biting; these multiply in the gut and pass forward via the proventriculus and salivary ducts to the salivary glands, where further development ensues. Glossinæ become infective in 3 to 7 weeks and remain so for life; they bite mainly in the daytime. *T. gambiense*, the central African type, is transmitted by *G. palpalis* and *G. tachinoides*; possibly the natural reservoir of infection is game, such as the reed and bush buck, etc., encountered near lakes and rivers by which these flies live, depositing their larvæ in shady, sandy soil. *T. rhodesiense*, on the other hand, is spread by *G. morsitans* and *G. swynnertoni* which are widely distributed independently of water. The reservoir of infection is the infected game of the area: Bruce identifies this disease with nagana and regards *T. rhodesiense* as identical with *T. brucei*. As the pathology and symptomatology produced by the two African trypanosomes are similar they may be considered together.

Pathology.—The lymph glands, which are at first swollen, congested and hæmorrhagic, later undergo degenerative changes and extensive fibrosis. Enlargement of the spleen due to lymphoid hyperplasia and proliferation of endothelial cells also occurs, while thickening of the capsule is common. In the late stages trypanosomes are demonstrable in the intercellular spaces of the brain and cord, the microscopical appearances of which resemble those of meningo-encephalitis and meningo-myelitis. Mott has stressed the resemblance to general paralysis, perivascular lymphocytic infiltrations being invariable. Neuroglial cell overgrowth is also characteristic, and diffuse glial proliferation affects both the white and grey matter in the cord: the ganglion cells show chromatolysis of their nuclei, most marked in the cerebral cortex, and endothelial proliferation in the arteries may occur.

Symptoms.—Two phases are recognised: (I.) a stage of trypanosome fever when the trypanosomes are demonstrable in the blood and gland juice; (II.) the sleeping sickness stage when the cerebro-spinal fluid contains lymphocytes, globulin and perhaps trypanosomes. The incubation period probably varies from 1 to 3 weeks, and occasionally an intense local reaction follows at the original inoculation site. In many respects trypanosomiasis resembles syphilis. (I.) *Trypanosome fever.*—This is invariably seen in Europeans, but not always in natives. Its main features are: (1) an irregular remittent or intermittent temperature low in the mornings, higher at night; apyrexial periods may occur, lasting for weeks. (2) A low tension, rapid pulse of 100 to 120 per minute, which tends to persist despite a fall in the temperature. (3) An increase in the respiratory rate to 20 or 30 per minute. (4) Patches of circinate erythema, involving mainly the trunk. (5) Localised puffiness and œdema involving the feet, legs and face: the skin may be dry and irritable. (6) Polyadenitis: enlargement of the posterior cervical glands (Winterbottom's sign) is very characteristic; the epitrochlear, axillary, supraclavicular and axillary glands may also be involved; they are soft, elastic, not tender, and do not coalesce or suppurate. (7) An enlarged spleen which is generally palpable. (8) Deep hyperæsthesia, especially over bones like the tibia and manifesting a definite latent period (Kerandel's sign). Long latent periods of several months (rarely several years) may elapse before the central nervous system becomes involved, and probably some cases undergo spontaneous cure where the virulence of the trypanosome is low. Once the stage of sleeping sickness has become definitely established, the untreated patient rarely survives for longer than a year. (II.) *Sleeping sickness.*—In the *earliest phase* the patient may complain of headache, lack of concentration, disinclination for work and insomnia, associated with loss of weight, enlargement of lymphatic glands and slight tremor of the tongue. In the *intermediate phase* the countenance becomes sad, apathetic and morose, laziness and emotional instability increase, and the patient is always dropping off to sleep, even in tropical sunlight or when eating. The speech becomes mumbled and slow, the gait shuffling, and fibrillary tremors of the tongue, lips and hands develop. The reflexes are exaggerated and Romberg's sign is present. In the *final phase* all these symptoms become more pronounced; muscular weakness is extreme, saliva dribbles from the mouth, bed-sores and flexure-contractions may develop, the patient becomes entirely bedridden, and coma and convulsions generally terminate the picture.

The classical picture of sleeping sickness described above represents that encountered in areas where the virulence of the trypanosome is high. Recent investigation has shown that in both East and West Africa many mild cases occur in which slight toxic features, such as headache and a little fever, are the only manifestations of the disease. Furthermore, people are known to have survived who have had the disease continually for 15 years or more. Lester points out that it is the severely infected patient, often with involvement of the central nervous system, who attends hospitals and dispensaries, and this has resulted in the commoner mild clinical infections remaining unrecognised.

Complications.—Intercurrent infections like dysentery and pneumonia often cause death, and, as in syphilis, abortion and still-births are not infrequent. Keratitis, iridocyclitis, and choroiditis occur, and during treatment with tryparsamide optic atrophy has to be carefully watched for.

Diagnosis.—Irregular fevers, especially if associated with cervical adenitis, should arouse suspicion in patients who have been exposed to infection, and under such circumstances laboratory assistance is invaluable. Autoagglutination of the blood is frequently observed. Trypanosomes may be found in thin or in thick blood films, or in smears from centrifuged citrated blood. Even more satisfactory is the method of gland puncture, provided the gland juice be aspirated in a dry syringe, when 87 per cent. of cases with adenitis show trypanosomes (Broden). Inoculation of white rats or guinea-pigs with blood or emulsified excised gland is also a very valuable procedure. Lumbar puncture is essential in later cases; typically the cerebro-spinal fluid, which is often under increased pressure, shows an increase in globulin and lymphocytes, and later in medium-sized and vacuolated mononuclear cells as well. The advanced cases show counts of from 15 to 100 cells per c.mm. Trypanosomes are often difficult or impossible to demonstrate, even after centrifuging the fluid, and animal inoculation.

Prognosis.—The prognosis is very hopeful in *T. gambiense*, provided modern treatment be commenced before the central nervous system is involved: after this it is more doubtful, though many cases recover. *T. rhodesiense* is a far more virulent type of disease, and most patients succumb despite treatment. Europeans appear to recover better than natives, probably because they suffer less from intercurrent disease and are treated under better conditions.

Treatment.—PROPHYLACTIC.—McLean, in East Africa, discovered that a population between 10–60 per square mile proved ideal for the spread of sleeping sickness, affording maximum contact between fly and man. By concentrating the population in certain areas in Tanganyika sleeping sickness was practically eradicated. Destruction of reservoir vectors, *i.e.* big game, has not proved satisfactory. Removal of forest and bush for 15 feet around lakes and rivers is a valuable measure with *G. palpalis*, but does not affect *G. morsitans*. Personal prophylaxis is important. White clothes are advisable; shorts should not be worn, and veils and gloves used when feasible. Where possible travelling should be done at night. Duke showed that, owing to its delayed elimination, 2 grams of germanin confers protection against either *T. gambiense* or *T. rhodesiense* for at least 3 months.

CURATIVE.—Several specific drugs are of proved value in trypanosomiasis:

(1) Suramin (Bayer 205, germanin), a complex organic urea compound

—is injected intravenously in a dosage of 1 g. at intervals of 2 or 3 days until a total of 10 g. has been administered. It is especially useful in sterilising the blood in early cases of both *T. gambiense* and *T. nigeriense*, but tends to produce albuminuria and casts in the urine. The patient should be kept at rest in bed, and throughout treatment the protein content of the diet should be limited owing to toxic effects on the kidneys.

(2) Tryparsamide (sodium N-phenylglycineamide-*p*-arsonate) is given intravenously at weekly intervals in doses of 20–40 mg. per kilo bodyweight (1·5–3·0 g. for an adult) until a total dosage of 30 g. has been administered. Children receive relatively larger doses. Untoward symptoms are jaundice and the much dreaded optic atrophy which not infrequently supervenes; its onset may be indicated by failing vision or contraction of the fields of vision, flashes of light, ocular pain, lacrymation and photophobia. Many cases of total blindness have been recorded. The greater the changes in the cerebrospinal fluid the greater the tendency to optic nerve degeneration. Although tryparsamide is less trypanocidal than orsanine for trypanosomiasis in the circulating blood, it has the advantage of acting on *T. gambiense* when the cerebral nervous system has become involved. It is not justifiable to conclude that cure has resulted until the cerebrospinal fluid has remained normal for 6 months, and when lumbar puncture shows it to be abnormal after treatment another course of treatment must be instituted.

(3) Orsanine (Fourneau "270") is the monosodium salt of 4-acetyl-amino–2 hydroxyphenylarsonic acid and is injected intramuscularly or intravenously in a dosage of 20–35 mg. per kilogram of body-weight (up to 2 grams for an adult). Injections are given once a week for 10 to 12 weeks. It produces rapid sterilisation of the peripheral blood but a very limited effect in the meningo-encephalitic stage of the disease.

In *Gambiense* infections, Yorke advocates orsanine or suramin in early cases showing a normal cerebro-spinal fluid, while in later cases with a pathological cerebrospinal fluid a course of tryparsamide is advised after a few preliminary doses of orsanine or suramin have been injected to produce peripheral sterilisation.

In *Rhodesiense* infections, early cases should be treated with suramin. Owing to the relative resistance of this trypanosome to the aromatic arsenicals the results with tryparsamide are much less satisfactory once there is pathological cerebrospinal fluid. The best results under these circumstances are obtained by combined treatment of suramin and tryparsamide. Whatever treatment is adopted, the patient's general health must be built up in every way and intercurrent disease eliminated.

Yorke and his colleagues have recently reported promising results with three trypanocidal diamidines—diamidino stilbene, diamidino diphenoxy propane and diamidino diphenoxy pentane. The dosage is 0·5 mg. per kilogram intravenously or 1·0 mg. per kilogram intramuscularly daily for 8 consecutive days. Rapid peripheral sterilisation occurs, accompanied by great clinical improvement, but the permanent results in patients with a pathological cerebrospinal fluid have not yet been determined. Patients with damage to the optic nerve resulting from the aromatic arsenicals should receive a course of sodium thiosulphate, 10 c.c. of a 20 per cent. solution being given intravenously on alternate days.

SOUTH AMERICAN TRYPANOSOMIASIS (HUMAN).

Synonyms.—Chagas' Disease; Coreotrypanosis; Schizotrypanosomiasis; Brazilian Trypanosomiasis.

Definition.—A disease occurring in parts of South America caused by the trypanosome, *Trypanosoma cruzi* (Chagas, 1909), which affects the muscles, myocardium and brain of man.

Ætiology.—The disease, which has been recorded in several states in Central and South America, affects children and adults of both sexes. *T. cruzi* is a short, broad trypanosome (20 μ long) with a central nucleus and large, ovoid, posteriorly situated kinetoplast. The disease is conveyed to man by certain reduviid bugs, of the genera *Triatoma, Rhodnius* and *Eratyrus*, which have imbibed trypanosomes during their meal of blood. After a developmental cycle of 6–15 days, metacyclic trypanosomes are discharged in the excreta and infect man via lesions in the skin or mucous membranes. In Brazil the chief vector is *Triatoma megista*. The trypanosomes are found in the peripheral blood only for a short time after infection, after which they assume a Leishmanial form within the cells of different organs where they undergo division, and from time to time pass back into the peripheral circulation.

Pathology.—The Leishmanial forms are found especially in the heart and voluntary muscles, also in the thyroid, supra-renals, ovaries, testicle and bone-marrow, where they multiply, causing cell destruction, cellular infiltration, hyperplasia of connective tissue and fibrosis. The central nervous system shows lesions resembling meningo-encephalo-myelitis. The spleen, liver and lymphatic glands are enlarged, and according to Chagas the thyroid is congested and perhaps goitrous.

Symptoms.—Recent work has raised considerable doubt on the validity of many of the thyroidic features (cretinism, myxœdema, etc.) associated with the chronic phases of this disease; Kraus attributes them to endemic goitre with superadded infection with *T. cruzi*. The incubation period is 8 to 10 days. The *acute type* occurs in infants of under 1 year and is characterised by fever with trypanosomes in the blood, enlargement of the spleen and lymph glands, puffiness and œdema of the face and swelling of the thyroid. A proportion of cases develop the picture of encephalo-meningitis and frequently die. The *chronic type* presents a symptomatology which up to the present has not been accurately determined. Five clinical groups have been described: (1) Pseudo-myxœdematous; (2) myxœdematous; (3) cardiac; (4) nervous; (5) chronic with subacute manifestations. Serious disturbance of heart rhythm and neurological manifestations with paralysis probably result from intracellular invasion with *T. cruzi*, but until more accurate information is available eliminating endemic goitre as an ætiological factor little can be said on this phase of the disease. Much chronic heart disease in Brazil, Uruguay and the Argentine is attributed to this cause.

Diagnosis.—In the early acute stages this is made by finding the trypanosomes in the peripheral blood, while occasionally puncture of the voluntary muscles may reveal the Leishmanial forms. Inoculation of guinea-pigs is sometimes successful, and a reliable complement fixation reaction has been

worked out by Machado and others, using extracts of heavily infected heart muscle or cultured trypanosomes.

Prognosis.—The prognosis in acute cases, especially where the central nervous system is involved, is grave.

Treatment.—PROPHYLACTIC.—Destruction of the reduviid bug vectors by chemical means, fumigation, etc., is necessary. Better houses and the use of mosquito nets are important factors in preventing infection.

CURATIVE.—No specific treatment is available, the various drugs successful in African trypanosomiasis being ineffective.

AMŒBIC DYSENTERY

Definition.—Amœbic dysentery results from infection of the colon with *Entamœba histolytica* (Schaudinn, 1903), and is characterised by an afebrile diarrhœa, three or more voluminous stools containing brownish mucus and dark red blood usually being passed daily. Latency is a marked feature, relapses are frequent, while amœbic hepatitis and liver abscess commonly occur.

Ætiology.—This disease is mainly distributed throughout the tropics and sub-tropics, but occasionally occurs in temperate regions. Both sexes and all ages are liable, though it is less common in young children. *E. histolytica* gains access to the body in its cystic form via the mouth in drinking water or food, especially vegetables, contaminated by convalescent or contact carriers, while flies either directly or indirectly may convey the infection. The cysts pass through the stomach safely, after which the walls are dissolved by the pancreatic juice, and the encysted amœbulæ escape and ultimately invade the colonic mucosa. During this stage it is the large, actively motile, tissue-invading amœbæ (20 to 30 μ in diameter), containing ingested red blood cells, which are present in fæcal mucus, but later, as the lesions become quiescent and begin to heal, precystic amœbæ appear in the excreta, originating superficially by binary fission from the more deeply situated tissue-invading forms. Precystic amœbæ are much smaller (7 to 18 μ in diameter), less actively motile, contain no erythrocytes, and must be distinguished from *E. coli*. Different races of amœbæ give rise to cysts of different size containing 1, 2, or 4 nuclei and the characteristic chromidial bodies; they are met with in the fæces of chronic cases and carriers (*vide* p. 264).

Clinical and epidemiological observations have suggested that *E. histolytica* may remain a somewhat inoffensive organism until its pathogenicity is changed by intestinal bacteria. Recent observations on kittens experimentally infected with *E. histolytica* also suggest that in the destructive processes accompanying successful invasion of the intestinal wall, a bacterial as well as an amœbic factor is implicated.

Pathology.—After passing into the glands of the large intestine, the tissue-invading amœbæ multiply, cause toxic degeneration of the lining cells, with blockage of the tubules and the production of slightly raised yellowish nodules (Wenyon). Simultaneously, the inter-glandular connective tissues are invaded, and a toxic, gelatinous necrosis is produced, characterised by an absence of polymorphonuclear leucocytes and occasion-

ally by thrombosis of adjacent mesenteric venules. Small abscesses form which rupture, producing superficial ulcers with undermined edges. The process now extends through the *muscularis mucosæ* to the submucosa, larger bottle-neck ulcers sometimes resulting which are even an inch or more in diameter, and are filled with mucoid material, cell debris and amœbæ. The brown mucus and degenerated blood so characteristic of the amœboid stool originate in such lesions. Following rupture of the primary ulcer others are similarly produced, the maximum involvement being in the cæcum, ascending and sigmoid colon, which may be considerably thickened, and the rectum. Ulceration rarely extends above the ileo-cæcal valve, and even in extensive colonic involvement the intervening mucosa does not generally appear inflamed. Frequently ulcers heal with pigmented scarring of the mucosa and thickening on the peritoneal surface, while in other instances ulceration extends to the muscular layers; adhesions may form, and more rarely sloughing and perforation may lead to a fatal peritonitis. Invasion of the mesenteric venules may produce so-called hepatitis (miliary amœbic abscesses), or solitary or multiple amœbic abscesses of the liver, lung, brain and spleen, the chief pathological feature of which is the presence of tissue-invading amœbæ in their non-fibrous necrotic walls.

Symptoms.—The incubation period varies from 3 weeks to 3 months. The onset is generally insidious, commencing with an afebrile diarrhœa; later, 3 or 4 bulky, fetid stools containing brown mucus and degenerate blood may be passed daily. Occasionally the onset is acute, as in bacillary dysentery, with fever, pain, griping and purging associated with the frequent evacuation of bloody, brown, mucoid stools containing *E. histolytica*; tenesmus occurs if the rectum be involved. As the condition progresses considerable weight is lost, the skin becomes dry and earthy brown, and anorexia, dyspepsia, anæmia of secondary type and a mild neutrophil leucocytosis may develop. Examination often reveals thickening and tenderness of the colon, especially of the cæcum and sigmoid. Sigmoidoscopy generally shows the typical amœbic lesions; in the early stages small superficial yellowish nodules and petechial hæmorrhages may be noted, while later painless yellow ulcers surrounded by zones of hyperæmia appear; scrapings reveal large tissue-invading *E. histolytica*. As a rule the intervening mucosa appears normal, but occasionally a generalised proctitis may be observed which completely clears up under emetine treatment.

Patients from the tropics may give no history of dysentery yet cysts of *E. histolytica* are found in the stools. In this group recurrent abdominal pain is often complained of, and physical examination may reveal localised tenderness over the cæcum, the transverse colon or the sigmoid. Nausea, flatulence and constipation are common, and though a few complain of diarrhœa this is not frequent. Sigmoidoscopy reveals no abnormality. Appendicitis, cholecystitis, gastric or duodenal ulcer, gastritis, or diverticulitis may be suspected; yet treatment with emetine-bismuth-iodide which eliminates the cysts from the fæces is frequently followed by the disappearance of gastro-intestinal symptoms and under such circumstances they can with justification be regarded as of amœbic origin.

Complications.—Post-dysenteric adhesions, retro-colic abscess, intestinal hæmorrhage and perforation with peritonitis may result by an extension of the ulcerative process. The appendix has been found involved

in 7 per cent. of cases. Amœbic hepatitis associated with fever, enlarged tender liver, shoulder pain and leucocytosis, and responding satisfactorily to emetine injections, is not infrequent, while liver abscess, often accompanied by rigors, sweating and involvement of the right base of the lung, may develop. If unrelieved the abscess may burst into the pleura, pericardium, stomach, or large bowel, etc., according to its anatomical situation. More rarely, amœbiasis of the brain, spleen, seminal vesicles and testicle has been recorded. Amœbic ulceration of the skin and subcutaneous tissues may develop around the sinus associated with a liver abscess, a colostomy wound or amœbic lesions involving the anus. Extensive gangrene involving the buttock, perineum and scrotum has been described by the Meleneys.

Course.—The majority of cases run a chronic course, and even without specific treatment the tendency for amœbic dysentery is to improve temporarily, but relapses are frequent and very characteristic of the disease. Latency is marked, and contact carriers are frequently encountered who never suffered from dysentery.

Diagnosis.—The diagnosis is made by finding the large invading-tissue amœbæ in the fresh mucus in acute cases, and the precystic forms or cysts in the fæces of chronic cases and carriers. Four other forms of amœbæ, non-pathogenic to man, occur in the fæces, namely *Entamœba coli*, *Endolimax nana*, *Iodamœba bütschlii* and *Dientamœba fragilis*; these have to be differentiated from the tissue-invading and precystic forms of *E. histolytica* in fæcal examinations. Not infrequently, scrapings obtained during sigmoidoscopy reveal amœbæ despite previous negative reports on the fæces, and in any case of doubt instrumental examination should be carried out. Cytologically fewer pus cells are present in amœbic exudate than in bacillary dysentery, and Charcot-Leyden crystals also not infrequently occur. *E. histolytica* has been successfully cultivated on special media; the amœbæ feed on bacteria, starch granules and red blood cells where available, but the method as yet is hardly applicable to routine work. X-ray examination after a barium enema eliminates many other lesions entering into the differential diagnosis, while in distinguishing malignant disease, chronic bacillary dysentery, ulcerative colitis, bilharzial and balantidial ulcerations of the colon from chronic amœbiasis, sigmoidoscopy, reinforced by laboratory methods of examination, becomes indispensable. A valuable complement fixation reaction has been perfected by Craig using an alcoholic extract of cultures of *E. histolytica* as antigen. In some 90 per cent. of cases yielding a positive reaction *E. histolytica* or cysts were demonstrated.

Prognosis.—With modern methods of treatment uncomplicated cases of amœbic dysentery almost invariably recover, and a large proportion are permanently curable. The prognosis is naturally more serious where complications like liver abscess exist, and here one or more aspirations generally suffice, unless secondary bacterial infection has ensued. Colonic perforation with peritonitis is frequently, and brain abscess invariably, fatal.

Treatment.—PROPHYLACTIC.—As the disease is acquired by fæcal contamination of food and water, it becomes important to ascertain that personal servants and cooks are not carriers. Food should be protected from flies, and measures should be taken to avoid contamination of water and uncooked vegetables.

CURATIVE.—Long before amœbic and bacillary dysentery were differenti-

ated, ipecacuanha was recognised as effective in certain cases. Later, one of its alkaloids, emetine, was proved of great value by Rogers in India, and more recently other preparations, including bismuth-emetine-iodide, emetine periodide and auremetine, have been introduced. The toxic properties of emetine and its compounds should never be forgotten, and during intensive treatment it is essential that the patient be kept in bed on a simple, non-irritating, low-residue diet, milk being citrated to avoid clot formation.

Emetine is indicated where the tissue-invading amœbæ have produced visceral complications like hepatitis and amœbic abscess, and also during the initial attack. Emetine hydrochloride is injected intramuscularly or subcutaneously in 1 grain doses daily for a period not exceeding 10 days in a normal-sized adult, but the dose should be decreased in debilitated persons and those of low body weight. Children receive a dose proportional to age, for those under 3 years never exceeding $\frac{1}{6}$ grain, and for those under 6 years $\frac{1}{3}$ grain per day. Emetine is a muscle poison and, owing to the cumulative action of the drug, treatment should not be repeated within 2 to 3 weeks. Diarrhœa is commonly induced, and toxic symptoms include asthenia, cardio-vascular depression, low blood pressure, tachycardia, extra systoles, extreme muscular weakness causing paresis or even paralysis of the limbs; death may occur from cardiac failure, with paroxysmal tachycardia or auricular fibrillation.

Emetine-Bismuth-Iodide (E.B.I.).—This drug is preferable to emetine hydrochloride in chronic cases and carriers showing cysts, but it has the disadvantage of causing considerable nausea and vomiting, and is best given on an empty stomach late at night in gelatine capsules, 4 hours after the last feed. Phenobarbitone (gr. 1) or tincture of opium (min. 15) is given half an hour previously when necessary. Nightly doses, of grs. 3, are given for 10 to 12 doses, the total course varying from 30 to 36 grains. During the course patients often lose weight at the rate of $\frac{1}{2}$ lb. daily, and usually there is a definite fall in blood pressure and slowing of the pulse. Emetine periodide (E.P.I.), in capsules in a dosage up to grs. 6 daily, for 10 days, is also effective; it tends to cause less vomiting than E.B.I.

Carbarsone, which is a pentavalent arsenical, is an effective amœbicide for both vegetative forms and cysts, and is less toxic than stovarsol, which it is largely superseding. It does not, however, cure hepatitis or amœbic abscess. The drug is administered in pulvules containing 0·25 g., one pulvule being given twice daily after food for 10 days. Carbarsone can be used in ambulatory cases on a normal diet, and from these points of view possesses distinct advantages over the more toxic emetine preparations.

Chiniofon.—Chiniofon (yatren) is an iodine-oxyquinolin-sulphonic acid combination, and can be given by the mouth or as a retention enema. The adult dose is $\frac{1}{2}$ to 1 g. of the powder in gelatine capsules thrice daily for 10 days, repeated if necessary after a week's interval. If given *per rectum* the bowel should be first washed out with 1 pint of 2 per cent. sodium bicarbonate solution to remove mucus, and an hour later 200 c.c. of a 2·5 per cent. solution of chiniofon is run into the rectum and retained for as long as 8 hours if possible.

Combined treatment.—The most favoured combination in cyst cases consists of retention enemas of chiniofon in the morning and E.B.I. at night, or a course of the double iodide followed by carbarsone. During convales-

cence a non-irritating low-residue diet reinforced with vitamins is advisable, and alcohol should be avoided; meat is allowed once daily. The results of modern therapy are as a rule satisfactory, though relapses may occur, necessitating further courses of treatment, no matter what drug is used.

Surgical complications.—Emetine should always be given in hepatitis and also in amœbic abscess before needling, to relieve congestion (Rogers) Open operation and drainage should be confined to abscesses secondarily infected with bacteria. Amœbic appendicitis is only part of an amœbic typhlitis, and responds satisfactorily to emetine. Perforation is almost invariably fatal, unless immediately operated on.

For Bacillary Dysentery, see p. 118.

CILIATE DYSENTERY

Definition.—An ulcerative condition of the colon caused by *Balantidium coli* (Malmstren, 1857).

Ætiology.—Human infections generally occur amongst those having occupational contact with pigs, which also harbour this ciliate; cases have been reported from Europe, America, Asia and Africa. The ciliate is egg-shaped, 50 to 80 μ long by 30 to 55 μ broad; large and smaller forms are described. At its anterior end is the peristome; its interior contains a sausage-shaped macronucleus, a micronucleus and vacuoles, while externally the whole body is covered with longitudinal rows of cilia. Encysted forms, 50 to 60 μ long, also occur in the fæces. As healthy carriers are frequently encountered, it is not improbable that there is some secondary bacterial or other factor which determines the pathogenicity of *Balantidium coli.*

Pathology.—The colon, and more rarely the ileum, show ulcers distinguishable from amœbic lesions only by the demonstration of *Balantidium coli*, which is found both in the cavity of the ulcer and the surrounding submucosa; it may also invade adjacent lymph glands, but not the liver.

Symptoms.—In many cases the disease remains latent and symptoms are absent. In others the onset is insidious, with loose motions, later followed by sanguineous, mucoid stools typical of chronic dysentery; anæmia may develop. Intestinal perforation has been reported, but never liver abscess.

Prognosis.—The mortality rate including latent cases is about 7 per cent. (Walker), but in those showing active dysentery it may reach 29 per cent. (Strong).

Diagnosis.—Sigmoidoscopy may show colonic ulcers, but diagnosis is dependent on demonstrating *Balantidium coli* or its cysts in the excreta, or in scrapings from the ulcers themselves.

Treatment.—Most of the remedies tried have not been satisfactory. Aguilar advises restricting carbohydrates and increasing protein and fresh vegetables. Stovarsol in doses of 0·25 g. (4 grains) twice daily after meals for one week or carbarsone in a similar dosage for 10 days holds out some prospect of cure. Methylene-blue by the mouth and as an enema (1–3000) has been advocated and Walker considers silver protein of value. High colonic

irrigation with solutions of iodine, quinine and silver nitrate have been recommended, but owing to the spontaneous disappearance of the ciliates from time to time the value of different remedies is difficult to assess.

FLAGELLATE DIARRHŒA

There are three common intestinal flagellates of man, *Giardia intestinalis* (Lambl, 1859) which inhabits the upper intestine, *Trichomonas hominis* (Lavaine, 1860) and *Chilomastix mesnili* (Wenyon, 1910) found in the cæcum and colon. Considerable controversy has arisen regarding their pathogenicity and, though admittedly they are more common in cases of diarrhœa than in healthy individuals, nowhere do they actually invade the intestinal mucosa. Encysted flagellates are frequently found in normal stools, and Dobell has pointed out that the free flagellate forms which are naturally adapted to a fluid medium only appear when the stools become liquid or loose. From a clinical viewpoint, however, *Giardia intestinalis* has some claim to pathogenicity.

Giardia Intestinalis (Lambl. 1859)

Synonyms.—*Lamblia intestinalis; Giardia lamblia.*

Ætiology.—This parasite inhabits the jejunum and duodenum and occasionally reaches the bile ducts. It is a pear-shaped flagellate (10 to 18 μ long $\times$ 5 to 10 μ broad), possessing a concave sucker on its ventral surface, and in the encysted form may persist for many years in the fæces. As with certain other flagellates decreased or absent secretion of hydrochloric acid in the stomach appears to predispose to infection, and after gastro-jejunostomy we have found them in aspirated gastric juice.

Pathology.—In animals the glands of the small intestine may be found packed with giardia, and though they never cause ulceration or hæmorrhage, hyperinfection may, as Wenyon points out, lead to surface irritation. It is probable that in this fashion catarrhal enteritis results.

Symptoms.—Though encysted forms are often found in the fæces in healthy individuals, periodic attacks of diarrhœa may occur associated with the passage of large quantities of clear mucus or ochre-yellow stools in which enormous numbers of free flagellates occur. The demonstration of these flagellates in the bile by means of a duodenal tube does not constitute evidence of invasion of the biliary passages and gall bladder, and the present tendency to attribute all manner of symptoms to Giardia infection is to be deprecated.

Prognosis.—This is good; fatal cases in man being unknown.

Treatment.—Mepacrine hydrochloride (atebrin) in a dosage of 0·1 g. t.d.s., p.c. for a period of 5 days eradicates Giardia infection completely.

G. Carmichael Low.
N. Hamilton Fairley.

F. RICKETTSIA DISEASES

INTRODUCTION

Rickettsia bodies are small, non-motile, Gram-negative bodies usually less than 0·5 μ in diameter. They are more or less pleomorphic, and are found in both host tissues and arthropod vectors. They can only be cultivated in the presence of living tissue, and are mainly located within mesothelial cells, either in the cytoplasm or nucleus. Ricketts (1909) first noted these bodies in guinea-pigs and monkeys with Rocky Mountain spotted fever, and since then several varieties affecting man have been described. Thus, classical typhus and Brill's disease are caused by *Rickettsia prowazeki*; Rocky Mountain spotted fever by *R. rickettsi*; murine typhus by *R. mooseri*; tsutsugamushi disease by *R. orientalis*; trench fever by *R. quintana*; and "Q" fever by *R. burneti*.

An ever-increasing number of typhus-like fevers is being described in different parts of the world caused by rickettsias, and carried by arthropods like lice, fleas, ticks and mites in which rodents play an important rôle as reservoirs of infection. They have been classified on a geographical basis, according to their insect vectors, or in terms of their agglutination reaction with X2, X19 and XK strains of *Bacillus proteus*.

The ætiological relationship, if any, between the rickettsias and the various strains of *B. proteus* which have from time to time been isolated from typhus cases and are agglutinated in different fashions by sera derived from typhus-like patients, remains undetermined. It is probable that there is no ætiological relationship, the Weil-Felix reaction being merely an example of heterologous agglutination.

The Weil-Felix Reaction.—Suspensions of X19, X2 and XK strains of *B. proteus* are now employed in this agglutination test. Originally the reaction was carried out with living suspension, but now the alcoholic method, which destroys the flagella and preserves solutions of "O" antigen for six months, is used. In general it may be said that X19 is the main antigen for louse and flea-borne typhus, XK for mite typhus, while the sera from patients with tick typhus, as a rule, react in low titre to all three strains. The serum from patients with "Q" fever, however, does not react with any of these strains. Felix thinks the strain forming the main antigen for the tick-borne group has yet to be discovered.

For clinical purposes, a rising titre exceeding 1 in 100 may be taken as diagnostic. The test should be made as early as possible in order to estimate subsequent rises in titre. A significant rise rarely occurs during the first week, but it is generally well established by the tenth day. The maximum titre of 1/1000 to 1/10,000 may not be attained until convalescence, after which the reaction weakens and gradually becomes negative.

Though the test is of little diagnostic utility during the first week and may occasionally fail to reveal agglutinin in significant titre in severe cases until convalescence is reached, it is a reliable test of very real clinical value. Non-specific stimulation of the proteus "O" agglutinin in other bacterial infections of man rarely occurs.

Megaw has suggested the classification of typhus and the typhus-like fevers in terms of the host vector, and this will be adopted as being the most suitable classification for present purposes.

FLEA TYPHUS

Synonyms.—Murine Typhus; Hone's Disease; Ship Typhus; Typhus Murin; Endemic Typhus; Urban Tropical Typhus; Shop Typhus; X19 Tropical Typhus.

Definition.—A mild typhus-like fever, with a world-wide distribution, generally occurring in non-epidemic form, and caused by *Rickettsia mooseri*. It is conveyed to man by the rat flea, *Xenopsylla cheopis*, from infected rats or other rodents which are natural reservoirs of the disease.

Ætiology.—That some connection might exist between the handling of grain and rats was first suggested by Hone (1922) in South Australia. Maxcy (1926) suggested that the sporadic typhus-like fever of North America was conveyed by fleas from infected rats to man, and Dyer and others (1931) found that fleas collected from rats and injected into guinea-pigs produced the disease. Nicolle (1933) described the same disease under the title "*Typhus murin*" in sailors in French war-ships in the Mediterranean.

R. mooseri has a similar morphology to *R. prowazeki*, which causes epidemic typhus, and the Weil-Felix reaction with X19 strains is similarly positive in the two diseases. The two rickettsias are differentiated by the fact that *R. mooseri* gives a positive scrotal reaction when inoculated into guinea-pigs. However, it has recently been found in Mexico that a strain which at first gave a negative scrotal reaction, later gave a positive reaction after repeated passage through these animals. *R. prowazeki* and *R. mooseri* may therefore be identical and epidemic typhus have a murine origin, the strain being modified by repeated passage through man. Similarly, Brill's disease was at one time regarded as a variety of flea-borne murine typhus, but Zinsser has proved that in America it is really a mild recrudescence of louse-borne typhus occurring in carrier immigrants who had suffered from epidemic typhus contracted in Europe as long as twenty years previously.

Pathology.—Patients rarely die with flea-borne typhus, but there is no evidence that the lesions differ from those of mild epidemic typhus. In infected animals the lesions are very similar to those caused by *R. prowazeki* except in the guinea-pig, where the scrotum becomes dusky red, swollen and inflamed, the tunica is thickened and may show hæmorrhage and exudate, and the testicle is swollen. This lasts some four days, is known as the Neill-Mooser reaction, and is feeble and inconstant with *R. prowazeki*.

Symptoms.—The incubation period is generally 8 to 14 days, but exceptionally it may be 3 weeks. The onset is generally rapid, and the clinical picture similar to that of mild epidemic typhus, the temperature rising to 102° to 103° F. and persisting for about a week; shivery feelings, headache and pains in the back, and cough may occur. The face becomes flushed and the conjunctivæ are somewhat injected, but not to the degree seen in classical

typhus. A macular or papular rash may appear about the fourth or fifth day, but even in Europeans it is faint, while in dark-skinned races it may not be visible at all. Complications are generally absent, and convalescence uninterrupted and rapid.

Diagnosis.—A history of association with rats known to harbour the disease, the mild nature of the fever, and the strongly positive Weil-Felix reaction to X19 strain of *B. proteus* and negative response to XK will enable a diagnosis to be made in most cases. Though the malady cannot be differentiated from Brill's disease on these grounds, inoculation of rats which are very susceptible to flea typhus will settle the question, for rats are resistant to the virus of Brill's disease.

Prognosis.—The mortality ranges from 1 to 4 per cent., except in cases of the Mexican *Tabardillo*, which may be as fatal as classical typhus. Mooser holds that Tabardillo can be transmitted by lice as well as fleas, so its status is problematical.

Treatment.—Prophylaxis consists essentially of rat destruction and the avoidance of contact with rats. Vaccines of formolised suspension of Mexican murine virus from injected guinea-pigs have been employed by Zinsser and Castenada, with promising results. Experimentally, immunity is good against the murine strains, but only partial against classical typhus. Nicolle and Laigret's vaccine prepared from the brains of guinea-pigs or rats injected with the Tunis strain of murine typhus is also used to immunise man against both murine and epidemic typhus.

No specific curative treatment is known. The measures outlined in the treatment of louse-borne typhus are applicable.

MITE TYPHUS

A number of varieties of mite typhus has been described due to the one virus, *R. orientalis* or *R. tsutsugamushi*. For many years the scrub or rural form of tropical typhus described by Fletcher in the Federated Malay States, and transmitted by *Trombicula deliensis* from infected rats, was regarded as differing from tsutsugamushi disease inasmuch as there was supposed to be an absence of a primary lesion, lymphangitis and bubo. Lewthwaite and Savoor (1940) have now identified the two viruses, and shown that in rural typhus there may be either a persisting necrotic ulcer or a fleeting papular lesion which often escapes recognition by its disappearance before the onset of other symptoms. The local lesion is common in the white-skinned European and rare in the dark-skinned Tamil. In Sumatra the pseudo-typhus of Deli, transmitted by *Trombicula deliensis* from infected rats, is also identical with tsutsugamushi; though the mortality is only 5 per cent. in the indigenous population, it may be as high as 40 per cent. in Europeans. Similarly, Mossman or coastal fever of Queensland is a mild type of mite-typhus conveyed from rats by the mite—*Lælaps australiensis*; sugar-cane workers are especially affected. Lymphangitis and lymphadenitis are common, but the primary lesion, with its black central eschar and surrounding red areola, has been noted only occasionally.

Tsutsugamushi or Japanese river fever will be described as the type for mite typhus.

Tsutsugamushi Disease

Synonyms.—Japanese River Fever; Pseudo-Typhoid of Deli; Mossman or Queensland Coastal Fever; Rural or Scrub Tropical Typhus; Sumatra Mite Fever.

Definition.—An acute febrile disease of the typhus group often associated with a local ulcer, lymphangitis, adenitis, and an erythematous eruption. It is caused by *R. orientalis*, and in Japan is transmitted from infected field mice by the bite of a larval mite—*Trombicula akamushi*.

Ætiology.—The disease occurs commonly in July and August amongst harvesters handling the hemp crop in the Island of Nippon, Japan. It is also encountered in Formosa, Korea, China, Malaya, the Philippines and Sumatra. The disease is primarily an epizootic in mice, rats and possibly other rodents. In Japan the field vole, *Microtus montebelli*, is the reservoir host. Trombiculid mites pass through four stages in their development, but it is only the larval stage of *T. akamushi* or *T. deliensis* which can transmit infection to man.

Pathology.—Hæmorrhages into the serous membranes, splenomegaly, pulmonary congestion, adenitis, especially involving the thoracic and mesenteric lymph glands, cloudy swelling of the kidneys and liver, and myocardial degeneration may be found at autopsy. A local necrotic ulcer, with adenitis, is often present. Rickettsial bodies are generally demonstrable in the vascular lesions of the brain; they are common in the cytoplasm of the endothelial cells of the capillaries and smaller arterioles.

Symptoms.—In the Japanese form of the disease a small papule generally appears 2 or 3 days after attachment of the larval mite to the skin, especially that of the axillæ, genitals, or limbs. The papule may subside, or become pustular and form a necrotic ulcer some 6 to 8 mm. in diameter, surrounded by a red areola. Within the incubation period the lymph glands draining the bitten area become tender, painful and enlarged, and generally there is an associated lymphangitis.

Fever commences some 5 to 14 days after the bite, and the onset is generally sudden, with shivery feelings or rigor, headache, giddiness, malaise, and perhaps vomiting and pains in the chest. Sometimes there is a period of malaise and mild headache for 2 or 3 days prior to the onset of fever. Injected conjunctivæ, a furred cracked tongue and constipation are common, while hyperæsthesia, deafness, sweating, cough and signs of bronchial irritation may develop. Diarrhœa occurs in some cases. About the seventh day a dark macular rash appears on the face, later spreading to the limbs and trunk; it may be papular, but never becomes petechial. It lasts about 5 days, and, unlike the rash of Rocky Mountain spotted fever, does not tend to involve the hands and feet. The spleen is demonstrably enlarged in over half the cases, and generalised slight enlargement of the axillary, cervical and groin glands is not infrequent.

During the second week the fever is higher (103°–104° F.), prostration and mental symptoms such as insomnia are more marked, and should delirium or coma develop the outlook is grave. The blood pressure is low, there is considerable loss of weight, and the knee jerks are often absent. Leucopænia is the rule, and a mild grade of albuminuria common. The duration of the fever is from 2 to 3 weeks, the temperature reaching its maximum about

the fifth day, and falling by lysis or by crisis after disappearance of the eruption.

Abortive cases with adenitis and transient fever sometimes occur, and patients may remember removing the larval tick from the place where the ulcer subsequently developed.

Complications.—These include acute bronchitis, broncho-pneumonia, parotitis, phlebitis, and myocardial degeneration with heart failure.

Diagnosis.—Typhoid and para-typhoid fevers, and leptospirosis may simulate typhus. The presence of a necrotic ulcer, with adenitis, followed by fever, should enable a clinical diagnosis to be made in patients whose occupation is liable to bring them in contact with larval mites. Where the local lesion and adenitis are absent or inconspicuous a Weil-Felix reaction, positive to OXK and negative to OX2 and OX19 strains, would clinch the diagnosis. In Malaya, urban typhus has to be differentiated; here the Weil-Felix is positive with OX19 type, while male guinea-pigs inoculated with the blood taken early in the disease produce scrotal swelling, which does not occur in tsutsugamushi.

Prognosis.—The development during the second or third week of delirium and coma, myocardial failure, or broncho-pneumonia is an unfavourable feature. In Japan the mortality rate is about 30 per cent., varying from 20 to 50 per cent. in different reports. In Malaya it is now about 15 per cent.

Treatment.—Prevention consists essentially in measures designed to avoid contact with larval mites. Anigstein's vaccine consists of formolised saline emulsions of blood or tissue from patients or animals infected with Malayan tsutsugamushi. Some 200 and 400 million organisms are injected at weekly intervals, but no definite statement regarding its value can yet be made.

Curative treatment follows the lines outlined in classical typhus. No specific cure is available.

TICK TYPHUS

Several strains of virus are probably concerned in the causation of tick-borne typhus. The reservoir hosts are rodents and dogs, and, as Megaw points out, the epidemiological and clinical features of the different tick-borne diseases have sufficient in common to justify their being dealt with together. The agglutination reaction to all the strains OX2, OX19 and OXK tends to be of low titre, and serum from patients with "Q" fever does not react with any known strain of *B. proteus*.

Spotted fever of the Rocky Mountains was recognised long before any other types, and includes the milder Eastern type of spotted fever and possibly the more severe Sao Paulo fever. The latter is conveyed from rats to man by the horse tick, *Amblyomma cajennense*, and has a mortality rate of 70 per cent.; it closely resembles the graver cases of Rocky Mountain spotted fever, and its virus also immunises animals against the latter disease.

Fièvre Boutonneuse and the tick-bite fevers of Kenya and South Africa have much in common. Unlike Rocky Mountain spotted fever there is usually a sore at the site of the tick bite, and in experimental animals there is cross immunisation between boutonneuse and the South African virus.

Fièvre Boutonneuse occurs in most countries bordering on the Mediterranean, and is probably conveyed from dogs by the dog-tick, *Rhipicephalus sanguineus*. Clinically, it resembles the mild form of Rocky Mountain spotted fever, but the presence of a local necrotic ulcer of dark red areola, the more nodular nature of the rash, and the low mortality rate of 1 to 2 per cent. are outstanding differences. Furthermore, the virus of *boutonneuse* fever does not, as a rule, produce scrotal swelling in guinea-pigs, nor does it give cross protection against Rocky Mountain spotted fever virus.

"Q" fever, which is caused by *R. burneti*, gives rise to a mild typhus-like fever in man and inoculated guinea-pigs. In mice inoculated with human blood collected during the fever, *Rickettsiæ* are found in the spleen and suspensions obtained from mouse tissue are agglutinated in high titre by human serum from infected cases. The Weil-Felix reaction with the serum, however, is negative to all the known strains of *B. proteus*. In Australia the bandicott is a natural reservoir of infection and infected ticks of the species, *Hæmaphysalis humerosa*, have recently been collected from these animals. "Q" virus has also been found in *Dermacentor andersoni* by Dyer, in Montana, where the inhabitants of certain villages acquire the disease. Guinea-pigs, injected with a vaccine which will protect against Rocky Mountain spotted fever, are not protected against "Q" fever.

Rocky Mountain Tick Typhus

Synonyms.—Rocky Mountain Spotted Fever; Spotted Fever of Eastern Type.

Definition.—A non-epidemic severe typhus-like fever long recognised in the Rocky Mountains. It is generally unassociated with a local lesion or adenitis, and is transmitted to man from infected rodents by the bites of several different species of ticks including *Dermacentor andersoni*. The disease may have a high mortality.

Ætiology.—The disease primarily affects wild rodents, and, as shown by Wilson and Chowning (1904), is conveyed to man by ticks. Larval and nymph ticks transmit the virus from rodent to rodent, but human beings are usually infected by adult ticks of the species *Dermacentor andersoni*, *D. variabilis* and *Hæmophysalis leporispalustris*. Infected ticks transmit the infection to their offspring. It is said that a single infected tick may contain 15,000 infecting doses. The causal organism, *rickettsia rickettsi*, was described by Ricketts (1909) in the blood of guinea-pigs and monkeys infected with Rocky Mountain spotted fever. *R. rickettsi* produces a well-marked scrotal reaction in inoculated guinea-pigs, and can be demonstrated in the fluid exudate of the tunica vaginalis prior to generalised dissemination in the blood stream.

Most infections are found in people whose occupations brings them in contact with ticks. Where town dwellers are affected, dogs probably are implicated. Most cases occur in April and May in the Rocky Mountains, and in the summer in the Eastern States of the U.S.A.

Pathology.—Pathological changes include petechial hæmorrhages involving the skin and serous membrane, enlargement of the spleen and lymph glands, and degenerative changes in the kidneys, liver and heart. Proliferation of the vascular endothelium often leads to thrombosis and possible secondary gangrene. *R. rickettsi* is found within the nuclei of mesothelial

cells, not in the cytoplasm as with *R. prowazeki*. Vessels of the brain as well as the viscera are affected.

Symptoms.—The incubation period is from 3 to 14 days. A local lesion at the site of the tick bite with adenitis is rare. The onset is generally sudden, with headache, lumbar and generalised pains, and sometimes sweating, rigors, anorexia, malaise and vomiting. The tongue is coated, the conjunctivæ injected, and the temperature rises rapidly to 103° or 104° F., the maximum being reached in 3 or 4 days time. By then, in severe cases, the face is becoming dusky and a rose-red macular or papular rash appears. Later the macules turn darker, cease to fade on pressure, and may become obviously hæmorrhagic. The rash is first seen on the wrists and ankles ; later, it extends to the body generally, including the palms, soles and face. The fever lasts 2 or 3 weeks, and falls by rapid lysis. Constipation, restlessness and insomnia are usual, while severe cases may show stupor, delirium, coma and convulsions. Enlargement of the spleen is common, and may be an early feature. Later, there may be jaundice and hepatomegaly, and where the central nervous system is involved altered reflexes, and Babinski's and Kernig's signs may be elicited. A leucocytosis of 15,000 to 20,000 per c.mm. is not infrequent, but leucopenia may occur ; the lymphocytes are increased. Albuminuria is the rule in severe cases.

Apart from this average classical type there are abortive cases, with transient fever lasting 3 or 4 days ; ambulatory cases, with scanty rash and fever lasting 7 to 10 days ; and fulminating cases, which die with marked nervous symptoms either before the rash has appeared or with a hæmorrhagic type of eruption.

Complications and Sequelæ.—Convalescence tends to be prolonged, especially in severe cases. Bronchitis, pneumonia, femoral and other thromboses, parotitis, hæmaturia, epistaxis and malæna may complicate the picture. Iritis, nephritis, otitis media and gangrene of the fingers, toes, tonsils, prepuce and scrotum have been recorded.

Diagnosis.—The differential diagnosis includes epidemic and other forms of typhus, typhoid and the para-typhoid fevers, and cerebrospinal meningitis. Geographical considerations, the character of the rash, and the serological and other laboratory findings are of importance. Positive serological reaction may be obtained with OXK, OX2 or OX19 strains of *B. proteus*, but often reactions in significant titre are not evident until the fever is subsiding ; a steadily rising titre is, of course, diagnostic.

Prognosis.—The mortality rate varies from 5 to 50 per cent. in different geographical areas. Apart from fulminating cases, the onset of profound nervous symptoms, severe cardiovascular depression and a hæmorrhagic rash indicate a severe infection and imply a correspondingly grave prognosis.

Treatment.—In endemic areas tick-proof clothing should be worn and the body carefully searched for ticks ; iodine should be applied locally after their removal. A prophylactic vaccine has been prepared by Spencer and Parker in the form of a carbolised emulsion of heavily infected ticks. It gives satisfactory protection against both Rocky Mountain and Sao Paolo fevers. Medicinal treatment follows the lines outlined for louse typhus. No specific therapy is available.

G. Carmichael Low.
N. Hamilton Fairley.

LOUSE-BORNE TYPHUS FEVER

Synonyms.—Typhus Exanthematicus; Epidemic Typhus; Jail, Camp or Famine Fever.

Definition.—A highly contagious fever characterised by sudden onset, severe prostration, a characteristic rash, and termination by crisis about the fourteenth day. The infection is conveyed by body lice, perhaps through their bites, but more probably by cutaneous inoculation of their excreta by scratching. Head lice are also believed to be possible vectors. The disease is one of a group transmitted by lice, ticks, rat fleas, and larval mites.

Ætiology.—Most of the factors which conduce to the spread of typhus operate by their influence on the parasites by which the disease is conveyed. The lice pass directly from the sick to the healthy, or indirectly by means of garments, bedclothes and mattresses. Lice which have fed on infected persons can, after 8 or 10 days, transmit the disease and remain infective for the rest of their lives. Crowding of the sick together in dark, ill-ventilated rooms greatly favours the possibility of infection, whilst in the presence of free ventilation very close contact is necessary before the disease is contracted.

Exhalations from the lungs, emanations from the skin, and the excreta are believed to be capable of conveying the infection, and the bodies of those dead of the disease have been supposed to retain their infective powers until decomposition sets in. These beliefs, in view of the part played by lice, obviously need revision. Typhus carriers are always verminous persons. Clothes which harbour infected lice have often transmitted the disease to distant parts. The excreta of lice are also infective for a day or two, and may possibly be air-borne as dust and inhaled.

Typhus is a disease of cold and temperate climates; it occurs in those months of the year when confinement within doors and overcrowding are most likely. In hot climates frequent bathing, scantiness of attire, free action of the skin, and the lethal effect of high temperatures on lice are all factors which prevent its spread.

Predisposing causes are verminous infestation, overcrowding, and destitution. Epidemics are particularly liable to occur in times of war and famine. Typhus is rare in England, but endemic foci still persist in Irish and perhaps some Scottish towns. In Russia and Eastern Europe the disease is very prevalent, and a great epidemic ravaged Serbia in the early days of the War of 1914–1918. It has also been recognised in Canada, New York (Brill's disease), Mexico (where it is known as Tabardillo), Manchuria and other places.

Typhus attacks persons of all ages and both sexes. The greatest mortality is in those above middle age (at 50 years it may be 50 per cent., and between 75 and 80 years, nearly 85 per cent.); attacks in the young are less severe and very much less fatal. In populations where the disease is endemic attacks may be very mild, but when introduced into other places the type may prove excessively severe. In Brill's disease the mortality is less than 1 per cent.

Pathology.—The post-mortem appearances are those common to many acute infections and are not in themselves characteristic. Hypostatic congestion of the lungs and catarrh of the air-passages are common. The

absence of characteristic lesions in the bowel affords a distinction from typhoid fever. Beyond occasional meningeal congestion the central nervous system appears normal. Zenker's degeneration of muscle may be found.

Microscopical examination reveals the presence of nodules of endothelial proliferation in the small arteries of the skin and of the brain, also in those of the muscles and viscera.

Prime importance is attached to the presence of Rickettsia bodies (*Rickettsia prowazeki*). These are small and pleomorphic, not more than 0·3 by 0·4 μ in size. They are Gram-negative and stain by Giemsa's stain. Rickettsia bodies are found sparingly in the blood taken from a patient on the seventh to the twelfth day of the disease, and also in infected lice and their excreta. Similar bodies have been described in the vascular lesions and in the endothelial cells of the liver.

An agglutinative phenomenon which goes by the name of the Weil-Felix reaction affords a valuable means of recognising the disease. The reaction is named after two observers who discovered in the urine of patients suffering from typhus an organism of the Proteus group which is agglutinated in high dilution by the serum of those infected. The strain of Proteus concerned is known as the O variety of X19, and agglutinations have been obtained with dilutions of serum up to 1 in 30,000. Reactions in controls, if occurring at all, do not take place in dilutions exceeding 1 in 50 or, at most, 1 in 100. In half the cases of typhus the reaction is found by the fifth day, and in practically all by the tenth day, after which the titre rises for about a week. There is, however, no proof that Proteus X19 is capable of producing typhus, nor does it confer immunity to the disease.

The Wassermann reaction is almost always positive in typhus if the blood is examined before the crisis, but becomes negative again in convalescence (Bauer). In inoculated persons the titre of the Widal reaction for typhoid rises steadily.

Symptoms.—The incubation period in most cases is about 12 days. Eight to 10 days is a common interval when the disease is produced experimentally.

The onset is generally sudden, and ingravescence much more rapid than in typhoid. Distressing headache, giddiness, shivering or rigor, and frequently vomiting mark the accession. Pains in the limbs and back may be severe, and blunting of the mental faculties with great muscular prostration is evident from the first. The tongue is large and coated, but soon becomes brown, and finally may be dark and shrivelled. Appetite is lost, thirst is great, the bowels are generally constipated, and the urine high coloured and scanty, rich in urea and uric acid, but deficient in chlorides. Albumin may appear later and the diazo-reaction is very constant. The face is flushed or dusky, the features swollen and the appearance apathetic. The conjunctivæ are injected and the pupils contracted. Epistaxis may occur. The spleen may be palpable, but the abdomen is not distended. Even early in the disease, especially in alcoholic subjects, marked delirium, mania or stupor may be evident. Insomnia is present, or bad dreams disturb the rest. Tinnitus occurs, or deafness of nervous origin. The tongue is tremulous, and the gait tottering; if the patient has not already taken to his bed he usually does so by the third day of illness. The temperature may reach 104° F. by the first night; the acme, however, is generally attained on the third or fourth day.

Associated with the fever is a rapid soft pulse. Marked rapidity of the respirations is also noticeable and may lead to an erroneous diagnosis of pneumonia.

The fever (Fig. 5), which during the invasive stage may show remissions, after attaining its maximum, which may be as high as 105° or 106° F., shows little or no daily variation. At the end of the first week or a day or two later a sudden remission, which is rarely lasting, may occur (pseudo-crisis); from this period, however, the fever generally shows some abatement and terminates by a sudden or somewhat gradual crisis on the thirteenth to the seventeenth day of the disease.

The rash appears on the fourth or fifth day, first on the axillary folds, the sides of the chest and the abdomen. It avoids the face, which is merely

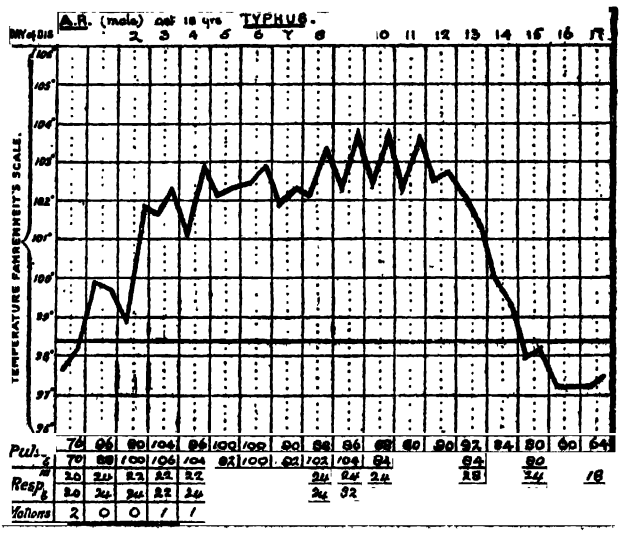

FIG. 5.—Typhus fever. Illustrating a somewhat gradual onset and abrupt termination by crisis.

flushed and congested, does not appear on the palate, and rarely on the palms and soles, but with these exceptions it may become general all over the body, although it is most profuse on the trunk, especially on the back. The three elements of which it consists are macules, papules and petechiæ. The macular elements of the rash generally appear before the papular elements and are much larger and blotchy; they appear to be in the skin rather than on it, hence the term subcuticular mottling which is applied to the appearance produced. These macules are best seen about the shoulders and axillæ, but often extend to the back and front of the chest, the thighs and arms. The papules resemble the rose spots of typhoid. At first they fade on pressure; later they may show petechiæ, becoming dull red or brown and indelible. They do not appear in successive crops. Purple petechiæ which resemble flea-bites and sometimes also purpuric patches are less constant. The latter indicate a severe infection, the hæmorrhagic character of which may be

confirmed by the occurrence of hæmatemesis, melæna or hæmaturia. Profusion of the rash in typhus is an indication of a severe attack. In mild cases the eruption is scanty, and in children it is very evanescent.

A leucopenia in the early stages is followed by anæmia and leucocytosis, in which polynuclears or monocytes may predominate.

The cerebro-spinal fluid may show a slight lymphocytosis, and also give a low positive Weil-Felix reaction. The globulin is increased.

Towards the end of the second week the patient in a grave case may enter on the second stage of his disease. There is less complaint of headache; delirium, if present, is less violent and of a muttering rather than maniacal type. Prostration may be extreme and sleeplessness pronounced. The face is dusky, sordes accumulate on the teeth, and a curious mousy odour emanates from the patient. Day by day the nervous depression increases and the patient lies helpless on his back with a tendency to sink down in the bed. The pupils are pin-hole, the eyes half open and fixed (*coma vigil*). Although deaf and unnoticing, he mutters incoherently and can be roused with some difficulty. Tremors of the tongue and tendons, and picking at the bedclothes are apt to occur. The pulse quickens and may reach 130 per minute. It is dicrotic or almost imperceptible. The heart's impulse is feeble and the first sound faint or inaudible. The blood pressure falls steadily. Acceleration of respiration is more than ever pronounced, 40 per minute not being unusual; the breathing is shallow, and hypostatic congestion of the lung bases occurs. The urine may be retained or passed into the bed, as also the fæces. Bed-sores are apt to form. The patient may pass away in coma, or hyperpyrexia may precede death, which may occur in the second week, usually it is said on the eleventh day.

On the fourteenth day, sometimes a little earlier, sometimes later, the crisis should occur. The condition suddenly improves; the temperature falls, sometimes abruptly, perhaps more frequently by a crisis which is a little more gradual. Sleep ensues and the patient awakes from his stupor with a moist tongue and skin, a clearer intellect and perhaps a slight critical diarrhœa. Inclination for food returns, but there is still extreme weakness. Some, failing to rally after the crisis, fall into a state of collapse. In less severe cases, where the typhoid state has not been pronounced, the crisis may occur rather earlier and recovery be much more rapid; this is especially the case with children.

Varieties.—Typhus may occur in forms which are characterised by extreme mildness or by fulminant severity. The milder types are particularly seen among the natives of localities where the disease is endemic, and in children. Of the severe types, that known as *typhus siderans* or *blasting typhus* is the most striking. In this form death may occur within 2 or 3 days of the onset. A meningeal variety, accompanied by head retraction, ptosis, squint and other nervous symptoms, simulates meningitis, which may indeed be present. Some cases are characterised by fierce maniacal delirium. Typhus also may assume a hæmorrhagic form, but this is uncommon. Relapse in typhus is almost unknown, and authentic second attacks are rare.

Complications and Sequelæ.—Respiratory complications in the form of bronchitis, broncho-pneumonia, or hypostatic congestion of the lungs are the commonest. Rarely laryngitis occurs and may lead to necrosis of the cartilages and œdema of the glottis. True lobar pneumonia is hardly ever

seen. Diarrhœa is sometimes troublesome; it may be accompanied by abdominal distension and the passage of blood. Femoral thrombosis, analogous to that of typhoid fever, is common. Septic or gangrenous infarcts may be formed in the lungs, and gangrene of the fingers, nose or pudenda may occur. Suppurative parotitis is a marked feature of the disease, and the inflamed gland may become gangrenous. Gangrenous bed-sores, too, are apt to form with great rapidity and pyæmic complications may ensue. When typhus is followed by hemiplegia or other forms of paralysis, thrombosis or embolism of cerebral arteries should be suspected. Mania, melancholia and dementia are occasional sequels but generally clear up, although they may take several months to do so. Amongst rarer complications may be mentioned nephritis, cystitis, orchitis, jaundice and meningitis.

Diagnosis.—For the Weil-Felix reaction a reliable smooth strain of *Proteus* X19 is requisite. A rising agglutination titre to this organism is most significant. Results with a titre of less than 1 : 200 should not be accepted as positive unless the titre has risen greatly since the onset. The agglutination may become negative in the third or fourth week of convalescence.

As compared with *typhoid*, the onset is more sudden, and prostration is earlier and more pronounced. The aspect is drunken, the face congested, the pupils contracted and the eyes suffused. Diarrhœa and abdominal symptoms are unusual. The eruption is more profuse and more widely distributed, and the spots, which are paler than those of typhoid, are accompanied by subcuticular mottling. The termination of the fever is more abrupt. Blood cultures and agglutination tests are of great value in distinguishing the two diseases, and to those acquainted with typhus the peculiar mousy odour, which is absent in typhoid, is of assistance. *Lobar pneumonia*, especially the apical form with slight meningeal symptoms, may be mistaken for typhus, but should be eliminated by careful and repeated physical examination of the lungs. The hypostatic pneumonia of typhus is bilateral and does not show frank signs of consolidation. Herpes may occur in both diseases. *Meningitis* is now easily distinguished by lumbar puncture and examination of the cerebro-spinal fluid. *Encephalitis lethargica*, with fever, headache and delirium, must be distinguished by the absence of the characteristic rash of typhus, the negative Weil-Felix reaction, and the supervention of such signs as ptosis, ophthalmoplegia, and characteristic lethargy from which the patient can be roused. The cerebro-spinal fluid may show a lymphocytosis, without globulin increase, or it may contain blood. *Uræmia* is sometimes confused with typhus, but is distinguished by the absence of fever and rash and the condition of the urine. Difficulty occasionally arises with a fading *measles* rash, but unlike the rash of typhus this invades the face. A history of catarrhal symptoms may also be obtained in measles. The *spotted fever of the Rocky Mountains* closely resembles typhus. In hot climates and on campaigns other possible sources of error in diagnosis are small-pox, relapsing fever (epidemics of which often coincide with those of typhus), sand-fly fever, and malaria. Influenza also may lead to difficulty.

Prognosis.—The mortality, which is low in childhood and adolescence, then progressively increases (see page 275). In aged patients, recovery is the exception. Clinical indications of gravity are persistent sleeplessness, marked subsultus, violent delirium or convulsions, evidence of a hæmorrhagic

tendency, a profuse petechial rash and continued high fever or hyperpyrexia. Failing circulation is shown by lividity, coldness of the extremities and hypostatic congestion of the lungs. Suppression of urine and uræmic symptoms are also of grave import. A blood urea of 90 mg. per cent. is unfavourable, and it may rise to 200 mg. in fatal cases. Gangrenous bed-sores, extensive parotid suppuration, pyæmic symptoms and peripheral gangrene are of bad augury. The disease is particularly deadly to alcoholics, and fat subjects. Doctors often fall victims.

Treatment.—PROPHYLACTIC.—Every effort should be made to get rid of lice. The patient should be stripped, the hair clipped short, and the body shaved and thoroughly washed before admission to a ward. The garments of attendants should be so arranged as to prevent as far as possible the risk of being bitten. The clothing of those infected, and of contacts, should at once be adequately sterilised and their living rooms and their contents disinfected. Cases of typhus are best treated in isolation hospitals, and when the disease is epidemic good results are obtained by forbidding movements of the populace in the infected areas. Injection of the blood serum of healthy convalescents is said to be a prophylactic.

By cultivating the virus in lice and emulsifying their mid-guts in carbolic solution Weigl produced a protective vaccine. This contains dead Rickettsia.

A quarantine of immediate contacts for at least 15 days is usually recommended.

CURATIVE.—This should be on the same lines as those adopted in typhoid fever. Free ventilation, tepid sponging night and morning, careful attention to the mouth and back, and the adoption of a fluid diet, consisting of milk, beef tea, fruit juices and plenty of water, are the essentials. The bowels are usually constipated and enemas should be used. The bladder should be watched; retention of urine may lead to great restlessness and constant overflow. When the temperature rises above 103° or 104° F., tepid or cold sponging should be repeated. In hot climates, exposure to undue heat has a very deleterious effect. For sleeplessness, paraldehyde is the most useful hypnotic, but requires to be given in large doses. Wildly delirious patients need some form of restraint, and in these cases hyoscine should be tried if other means fail. Frequent rectal salines or the administration of saline solution intravenously or subcutaneously are beneficial when toxæmia is extreme. The tendency to collapse after the crisis should be remembered, and patients carefully watched at this period. For further details of symptomatic treatment the article on typhoid may be consulted.

CHARLES R. BOX.

TRENCH FEVER

Synonym.—Volhynia Fever.

Definition.—A blood infection communicable from man to man by means of the louse (*Pediculus humanus*). Characterised by recurrent pyrexia, headache, giddiness, pain in the back, pain in the limbs, conjunctival congestion, sweating, moderate leucocytosis at the height of the fever, and slight enlargement of the spleen.

The infection is often very persistent, and acute febrile relapses may

occur after months of quiescence. The disease was first recognised as a specific entity during the War of 1914–1918, when it appeared on all the European fighting fronts—800,000 being the approximate number of cases occurring in France among the Allies during 4 years, and sporadic infections have been reported among those coming into contact with returned troops in England and elsewhere.

Ætiology.—Trench fever being transmitted by lice alone, its occurrence depends on the presence of these insects and of human carriers of the infection. As with other insect-borne diseases, considerable numbers of the vector are required before an epidemic is produced, and close contact between human beings is necessary to facilitate the transference of the lice. Both

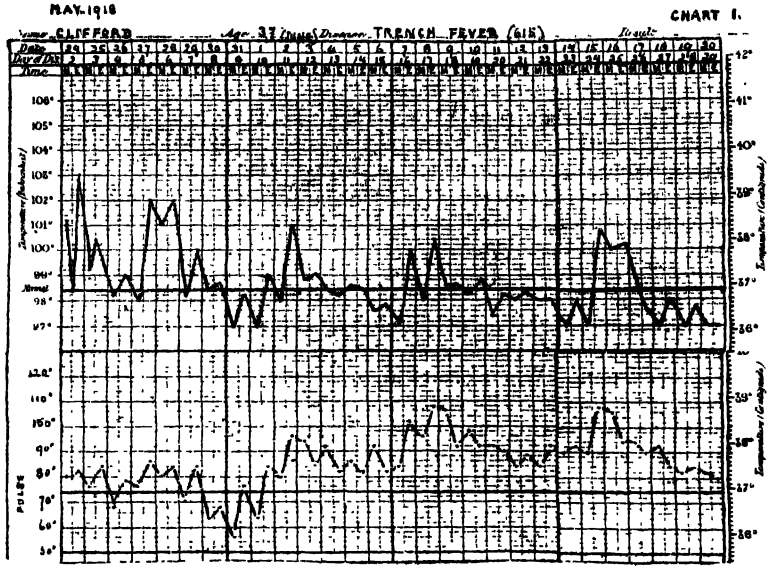

FIG. 6. Trench fever. Typical temperature and pulse curves.

the body louse and the head louse are capable of conveying infection. The disease is conveyed by the excreta or crushed bodies of infected lice; the virus may enter through the broken skin or unbroken conjunctiva; rubbing and scratching promote infection, but the bites of the lice may cause a sufficient lesion to enable infective material to enter the body.

The causal organism.—No observer, as yet, has succeeded with certainty in demonstrating the organism of trench fever in stained or fresh blood preparations, though it is known that the blood of patients is infective both during fever and in the afebrile intervals and for many months if symptoms persist. Further, the blood plasma has been shown to contain the infective agent, which in this condition is capable of passing through a Pasteur-Chamberland filter (L) with 740 mm. of mercury vacuum. Arkwright, working with excreta from lice fed on trench-fever patients, has shown that the

infectivity of the excreta for man varies very closely with the presence or absence of rickettsia bodies.

Pathology.—Very little can be said under this heading. Though German writers refer to fatal cases of trench fever, no reliable accounts of post-mortem examinations are available, and we have no knowledge of any death caused by this disease.

Symptoms and Course.—The incubation period, as evidenced by experimental infections with louse excreta, is most frequently 7 to 9 days, but the period has been prolonged to 16 days when minute doses of louse excreta have been inoculated.

The onset of the disease is sudden in the majority of cases, though about 25 per cent. of all patients complain of prodromal symptoms, such as headache, generalised pains, weakness, diarrhœa, constipation, restlessness, or insomnia, for a day or two before the temperature rises. In some instances the onset is quite dramatic in its suddenness, the patient collapsing while out walking, or even falling from his horse.

The temperature rises rapidly as a rule, and may reach 103° to 104° F. (39·4 to 40° C.) within a few hours of the onset of symptoms. A study of the chart reproduced (Fig. 6) will reveal the main features of the course of the fever; the curve may be extremely erratic. The pulse is usually accelerated, its curve corresponding to that of the temperature, its rate varying from 90 to 120 in men of military age.

In the fully developed attack, the patient's three chief complaints are headache, pain in the small of the back, and pain in the limbs. The headache is most commonly felt across the forehead and behind the eyes; usually one of the earliest symptoms, it is often one of the most severe, persistent, and commonly recurrent. When occipital, it is often accompanied by stiffness in the back of the neck. The character of the pain in the limbs is twofold: (*a*) Dull aching or gnawing, more or less continuous, always worse at night; and (*b*) acute pain—shooting or stabbing—which may last many hours, especially at night. This latter pain is nearly always felt in the bone and, most frequently, in the tibia. There is no part of the body which invariably escapes from pain. After a few days, however, the "pain all over" subsides and localised pain becomes prominent. The loins and lower limbs are most often affected. Pain is usually, but not invariably, symmetrical; its situation may vary from day to day. The pain complained of in the left hypochondrium points, in most instances, to involvement of the spleen. In early cases the splenic region is frequently so tender that examination by palpation is impossible, on account of stiffness of the muscles over the organ. When the spleen is felt, its edge is well-defined and firm. Its actual size, however, varies from day to day in the early stages, and does not remain constant until late in the disease. It is often observed to increase suddenly with the relapses and decrease during the afebrile periods (Day). Areas of tenderness are frequently associated with the pains, and may involve the spleen, tendons, bones, or joint cartilages. The nerve trunks themselves do not appear to be involved. Such tenderness may occur independently of pain, or vice versa, and either or both may persist for long periods after the fever has subsided. The extent of the areas of tenderness usually increases with exacerbations of the disease, which exacerbations may be entirely afebrile. As with the pain, the areas of tenderness are usually bilaterally symmetrical,

the skin from knee to ankle along the outer border of the tibia being most frequently involved.

The general appearance of the patient during the acute fever suggests a condition of extreme discomfort. He is restless, moving constantly to relieve the pain, and always failing to find comfort. A fairly constant feature of the initial attack is a mild degree of conjunctival congestion; it is usually transient, but frequently recurs with subsequent rises of temperature; this "pink-eye" is not accompanied by increase of secretion. At first the tongue is slightly coated with cream-coloured fur, though there is nothing characteristic about its appearance: it soon clears, and remains remarkably clean. A peculiar and very constant feature is the rapid alternations of shivering and sweating, such alternations occurring several times in the course of a single day or night. Profuse sweating, however, is rare. Rose spots upon the chest and abdomen are frequently seen during the first few days of fever. "They appear in crops, are fairly uniform in size (4 to 8 mm. in diameter), with fairly well-defined edges, varying in hue from bright pink at first to a dull red colour later. They disappear on pressure and are not raised, although vesiculation has been observed in a very few cases. They last from 6 to 48 hours and disappear suddenly, leaving no stain; at times they make their initial appearance during the relapses, which may be afebrile" (H. Fairley Marris).

The mental condition remains normal throughout the disease in the great majority of cases, though rarely there may be some delirium in the most acute attacks. The tendon reflexes are exaggerated, and a pseudo ankle-clonus is often found. During fever, lateral nystagmus on extreme deviation of the eyes is common. Frequency of micturition is complained of by about 13 per cent. of all cases, and is not associated with pain, but results in the passage of an increased amount of urine. A trace of albumin is often present. The polyuria occurs as the temperature falls.

The blood picture indicates abnormal activity of the bone marrow, and a moderate and rapidly varying leucocytosis precedes and accompanies the fever waves. The count rarely exceeds 20,000 leucocytes per c.mm. The increase of white cells is due to outpouring of immature polymorphonuclears up to 80 per cent. or more of the total. In the afebrile intervals the mononuclear elements are relatively increased. This last is probably a condition common to many soldiers in the field. In chronic cases the total of red cells is increased, the colour index as a rule being about 0·8.

Progress of the Case.—When a definite afebrile interval occurs between the initial fever and the first relapse, all symptoms usually subside as the fever abates, to return as the temperature rises. In prolonged cases, the patient's general condition obviously deteriorates and he presents an appearance of exhaustion. As relapse succeeds relapse the intervals bring less and less relief, though in some cases the later fever waves are accompanied by singularly few symptoms. The body weight steadily declines. Usually, after a period varying from a few days to about a fortnight from the onset of the disease, the acuteness of the patient's pain subsides, he sleeps well, and his appetite returns. There is even then generally some return of pain each night in some part of the limbs—most commonly the shins, calves, or ankles. If he be allowed to get up he finds walking increases the pain. During the next week or two, whether pyrexia recur or not, there are recurrences of symptoms

—especially leg pain, each exacerbation being a short replica of the original attack, or of some portion of it. In some cases such recurrences are few and slight, and the patient soon feels fit and complains of nothing but slight pain or still slighter tenderness in a limited area of the legs, from the knees downwards. In others the recurrence, even if quite late in the disease, as after months of quiescence, may be more severe than the original attack.

The Chronic Disease.—It has become evident, in a large proportion of the cases of trench fever invalided home, that there is a tendency to advance through a subacute towards a chronic condition, with symptoms of disordered action of the heart, and also in some of neurasthenia. Breathlessness on exertion, palpitation, præcordial pain, and giddiness are features of the subacute and chronic conditions. The temperature in these chronic cases varies considerably; definite fever waves lasting from a few hours to several days occur at irregular intervals, which frequently are to be measured in months.

Diagnosis.—The acute disease may be mistaken for the enteric fevers, malaria, cerebro-spinal fever, influenza, dengue, rheumatic fever, European relapsing fever, typhus, rat-bite fever, or mild infective jaundice with absence of jaundice and albuminuria. Trench fever in the chronic form is particularly liable to be mistaken for some form of cardiac disease, neurasthenia, myalgia or chronic rheumatism; and, in addition, must be differentiated from other chronic infections, such as malaria, and tuberculosis.

Prognosis.—Trench fever is practically a non-fatal disease, but may result in prolonged ill-health in from 10 to 20 per cent. of all those affected. A certain degree of immunity follows an attack of trench fever, more particularly when the attack has resulted in a complete clinical recovery; and it has been shown experimentally that such immunity may persist for six months.

Treatment. - It is a simple matter to free the individual from lice, and as regards the community this depends on successful organisation. The sick should be immediately and completely freed from vermin; but their isolation alone is not likely to control the spread of an epidemic, as mild cases are apt to escape recognition, and chronic cases remain infective for too long a period to permit of segregation till all danger is passed. The curative treatment is mainly symptomatic, the chief indication being to get the patient to bed as early as possible, and to keep him there for 8 days after the fever has subsided. In this way the incidence of chronic symptoms has been reduced. Chronic cases are best treated by healthy open-air exercise, with tonics and small doses of thyroid extract. Even when complaining of shin pain it is a mistake to allow such cases to live a sedentary indoor life.

Recent observations connected with preventive inoculation against typhus may throw light on how trench fever can be controlled.

W. Byam.

G. INFECTIOUS DISEASES OF DOUBTFUL OR UNKNOWN ÆTIOLOGY

FOURTH DISEASE

Synonym.—Filatow-Dukes Disease.

Filatow and, later, Clement Dukes described an infectious disease which they considered distinct from scarlet fever and rubella.

It is most prevalent in spring and summer. Previous attacks of scarlet fever and of rubella afford no protection. Premonitory symptoms are absent or trivial, the first sign usually being a rosy red rash, slightly raised, which covers the whole body in a few hours. The temperature may range from normal to 103° or even 104° F. The fauces are red, the tongue clean or slightly furred, and the pulse only accelerated in proportion to the temperature. The posterior cervical, axillary and inguinal lymph glands are enlarged to the size of peas, hard and somewhat tender. The conjunctivæ are pink. Desquamation may ensue.

The incubation period is between 9 and 21 days, and infectivity lasts for 2 or 3 weeks.

Most authorities either reserve judgment or refuse to recognise such a disease, alleging that some of the cases are rubella and some mild scarlet fever.

INFECTIOUS ERYTHEMA

Synonyms.—Megalerythema Epidemicum; Fifth Disease.

A mildly infectious disease of which the ætiology and mode of transmission are unknown. With slight fever, a confluent rosy eruption appears on the cheeks, avoiding the circum-oral region. The hot swelling, with its well-defined edge, may suggest erysipelas. Discrete papules spread to the forehead and neck; on the next day they invade the trunk and limbs, mainly the latter. The extensor surfaces and the buttocks are sites of predilection. The papules by confluence form patches, which may assume annular or gyrate patterns, spreading at the periphery and fading at the centres. The eruption disappears rapidly from the face and trunk, but may persist on the limbs for a week or more, and may recur as the result of irritation in a manner suggestive of urticaria. Complications are extremely rare. The incubation period is from 6 to 14 days. There is a slight polymorphonuclear leucocytosis. In contrast with rubella, eosinophilia may occur and plasma cells are scarce.

GLANDULAR FEVER

Synonyms.—Infectious Mononucleosis; Monocytic Angina.

Definition.—An acute, febrile, infectious adenitis, with a characteristic increase of mononuclear blood cells. Recovery is the rule, and complications are rare.

Ætiology.—Glandular fever is, in all probability, a virus infection. Invasion takes place through the throat, the respiratory tract or possibly the bowel. Its prevalence is world-wide. The disease is limited to small commensal outbreaks, but sporadic cases are not infrequent. It chiefly attacks children and young adults, male patients preponderating. The incubation period is about a week; it may vary from 5 to 12 days. The duration of infectivity is unknown, but appears to be short.

Symptoms.—In children and adolescents the onset is sudden, with fever and faucial injection. Stiffness of the neck, slight dysphagia or follicular conjunctivitis may occur. A rapid swelling of the lymph glands under the upper half of the sternomastoid muscle sets in. By the second or third day the glands may attain a considerable size. They are discrete and scarcely tender. The skin over them is not inflamed. In some cases, however, a definite membranous angina is already present or supervenes, and glandular tenderness is more pronounced (*anginose form*). Although the glandular swelling is at first unilateral, the glands on the other side of the neck may enlarge in turn, and minor or even primary swellings of the posterior cervical, axillary and inguinal groups may occur. The adenitis is often accompanied by sharp pyrexia, the fever being irregular, and ranging from 100° to 103° F., or even higher. Exceptionally a fleeting erythematous or rubelliform rash appears. The adenitis of glandular fever may not be limited to superficial glands or even commence in them. Paroxysmal cough, dysphagia and, rarely, even pulmonary collapse may indicate involvement of the mediastinal groups. Gastro-intestinal symptoms, such as vomiting and abdominal pain, may accompany palpable swelling of the mesenteric glands. Appendicitis may be simulated. Slight enlargement of the spleen and of the liver is not uncommon; rarely jaundice ensues. In some cases a mild lymphocytic meningitis has been observed. The blood changes are diagnostic but may be very transient. After a fleeting polymorphonuclear leucocytosis or, rarely, a neutropenia, the count shows a characteristic increase in the numbers of the mononuclear non-granular cells. These may form 40 to 90 per cent. of the total leucocytes instead of the normal 20 per cent. The cells are not of uniform type, as in acute leukæmias. Aberrant cells, which in some respects resemble large primitive lymphocytes, and in some monocytes, or plasma cells, may preponderate. The total leucocyte count is rarely more than 12,000 to 18,000, but may be 30,000 or more. The red cells are not diminished in number.

Heterophile antibodies, which agglutinate the red corpuscles of sheep, appear in the blood serum. This constitutes the Paul-Bunnell reaction. It becomes positive with the appearance of the swollen glands. A titre of 1 in 100, or possibly less, is diagnostic of glandular fever. Appearing about the fifth day, it may persist for 1 to 4 weeks. Sometimes its appearance is delayed. It may also occur in serum sickness.

The lymphadenitis is characterised by hyperplasia of the reticulo-endothelium and germ-centres which may be packed with cells like those in the blood.

The febrile stage of the disease may last for 10 days or longer, and exacerbations of fever, with involvement of fresh glandular groups, may occur. The glandular swellings subside more slowly than the fever. A subacute or relapsing type with sweats and irregular pyrexia, resembling

Hodgkin's disease, has been described. The mononucleosis may be very transitory, or may persist for some time. Convalescence is slow.

In some cases, mostly adult, glandular fever may differ considerably from the disease as described above. There is a febrile onset, with malaise, muscular pains, headache and perhaps epistaxis, but no marked soreness of the throat. Shivering, or even rigor, may occur. Towards the end of the first or second week of fever, a scanty eruption of macules or papules, like those of typhoid fever, may appear on the trunk and perhaps the limbs. The diagnosis is established when glandular enlargement, usually less pronounced than in childhood, supervenes in the third week or later, and the fever assumes a remittent type. At this stage a relative or absolute mononucleosis is most likely to be discovered, and may be evanescent or very protracted. A membranous faucial inflammation may also now be found. The spleen may enlarge. Relapses may occur, and the fever has been known to persist for many months. In some cases the Wassermann, or Kahn, reaction becomes temporarily positive. A misleading agglutination with typhoid " O " antigen in low titres may occur. Very rarely petechial eruptions have accompanied the fever, and the bleeding-time has been increased.

Complications.—There may occur a slight temporary albuminuria, with a few tube casts, but in some 6 per cent. of the cases a benign hæmorrhagic nephritis ensues. Suppurative otitis and retropharyngeal abscess have been recorded. Suppuration of the glands is rare. Serous meningitis is exceptional.

Diagnosis.—The clinical course is so characteristic and the cervical adenitis so disproportionate to the faucial inflammation that suspicion of glandular fever should be aroused, throat swabs examined, blood counts made, and the Paul-Bunnell test applied. In the adult form, fevers of the enteric group can be excluded by the usual bacteriological and serological tests. In the membranous form, diphtheria is excluded by absence of the Klebs-Loeffler bacillus and of acute toxæmic symptoms, despite persistent membrane. Resemblance to rubella is sometimes close, but there are differences in the blood films, and the Paul-Bunnell test will decide. The paroxysmal cough and leucocytosis may simulate whooping cough but the Bordet-Gengou bacillus is absent, and the Paul-Bunnell test positive. Swelling of the salivary glands and even Mikulicz's syndrome have been reported in rare instances. In such cases, if authentic, mumps may be simulated. Vincent's angina may complicate glandular fever, but the occurrence of Vincent's organisms is now regarded as fortuitous. Acute leukæmia at its onset constitutes a very real difficulty, but the leucocytosis is usually far in excess of that of glandular fever and the cell type more uniform ; anæmia is progressive, and the issue fatal. Hodgkin's disease is a much more chronic and progressive affection, and lymphocytosis rarely occurs ; biopsy of a gland is the most certain diagnostic criterion. Tuberculous adenitis has a greater chronicity ; periadenitis with suppuration and other signs of tuberculosis may be present. Septic adenitis induces a polymorphonuclear leucocytosis, and may suppurate. Agranulocytic angina is characterised by a low leucocyte count and the disappearance of all granular cells. The differentiation of glandular fever with abdominal symptoms from appendicitis is based on enlargement of the spleen and other glands, the blood picture, and the Paul-Bunnell test.

Treatment.—This is symptomatic. Ultra-violet radiation is said to hasten resolution of the adenitis. In protracted cases, injection of the blood

serum of a convalescent may bring the disease to a termination. Good results are also claimed from injection of sulphanilamide. Isolation for 7 days after the subsidence of the fever and glandular swellings is deemed sufficient in the acute cases.

CHARLES R. BOX.

RHEUMATIC[1] FEVER

Definition.—An acute, specific disease, characterised by fever, arthritis and a special tendency to carditis.

Ætiology and Pathology.—The essential cause of the disease is unknown. That the *materies morbi* is microbic there can be very little doubt, and for these reasons: the clinical features of the disease bear a strong resemblance to those seen in diseases of undoubted microbic origin, and especially in septicæmia due to streptococci and to staphylococci; the curves of incidence of the disease rise and fall with the curves of incidence of scarlet fever and of erysipelas; and the disease, if not interrupted by treatment, runs a natural course.

The essential causative factors of the disease have formed matter for discussion over a long period and are still by no means settled. At present three hypotheses are prevalent.

(i) *That the disease is a streptococcal infection.*—The close association with scarlet fever and with tonsillitis, diseases having strong affinities with streptococci, gives support to this view. But the difficulties in its acceptance are numerous: blood cultures are almost uniformly negative, even at the height of severe cases; cocci are not demonstrated in what is regarded as the essential histological lesion of the disease, the Aschoff node; the joint lesions, however severe, never suppurate; it has so far not been possible to incriminate any special variety of streptococcus as being specific.

(ii) *That the disease is due to a virus.*—As to this, though the view harmonises in many ways with the known facts, there are no data giving positive support to it.

(iii) *That the disease is a state of allergy.*—Those who hold this view conceive a focus of streptococcal infection, usually in the tonsil, which gives rise to a general hypersensitiveness of the body, and that this state, given certain conditions not yet defined, manifests itself by the syndrome which we call acute rheumatism. This hypothesis is thought by those who support it to explain the diversity of cocci associated with the disease. But, as Dible points out, that hypersensitivity should arise from infection by a multiplicity of strains of streptococci, rather than from one particular strain, constitutes the main difficulty in accepting this theory. Other difficulties are found in explaining why this particular form of sensitivity should be confined to streptococci, and why so small a section of the community should be affected. In no known state of allergy is there a specific histological lesion, nor is there a tendency to endocarditis.

Although rheumatic fever is probably not a contagious disease, an

[1] The word "rheumatic" is used throughout this article to signify conditions strictly belonging, or allied, to rheumatic fever, and not to include any of the many states loosely described as "rheumatism."

epidemic of sore throats, or of scarlet fever, is prone to produce a crop of rheumatic cases.

The disease is more common in humid and temperate *climates* than in others; it is probably more common in Great Britain than anywhere else. It is an urban, rather than a rural disease. The home environment is important as a contributory causative factor: bad general hygienic conditions predispose to it. The *sexes* are affected almost equally, but there is a slight preponderance in males, no doubt owing to their greater tendency to exposure. Rheumatic fever is pre-eminently a disease of pubescents and young adults, but it occurs at all *ages*, though it is uncommon in infants and in the elderly. If a person has had recurring attacks up to the age of 40, he is prone to them afterwards, but otherwise the susceptibility to the disease becomes greatly diminished after the age of 30. It is one of the striking facts of medicine that there are rheumatic families, in whom the tendency to the disease is highly marked. A certain *complexion* is common in them: a clear skin, with fair—often rufous—colouring.

Exposure, *fatigue* and *damp* are precipitating causes of the attack: a railway journey in wet clothes after muscular exercise, or sleeping in a damp bed, is a not unusual event in the patient's history of the onset. But it is equally true that many attacks come on in the absence of all these factors; indeed, attacks are not at all infrequent in hot weather. *Autumn* provides more attacks than any other season of the year.

Histological Morbid Anatomy.—A small cellular nodule, which is demonstrable in many cases of the disease, is thought by a number of observers to be specific. It is usually fusiform in shape, and consists of a fibrous matrix with many small round cells and some large cells, most of which are mononuclear. Later, this nodule becomes entirely replaced by fibrous tissue. Wherever this lesion is found, whether in the connective tissue of the heart muscle, in the synovial membranes or in the subcutaneous tissues—allowing for differences in the texture of the tissues themselves—these histological features are essentially the same. In the myocardium this lesion is easily recognisable ("Aschoff's node").

Symptoms.—In adults the onset is usually abrupt, with the sense of chill, accompanied almost at once by pains in the joints, the knees and ankles being the commonest. One or two joints usually precede the rest in order of invasion, to be quickly followed by others: wrists, shoulders, hips, neck, tarsus, metatarso- and metacarpo-phalangeal joints. Some degree of sore throat is very common, and may be a marked feature; when this is so, the tonsils usually show the redness and swelling more than other parts. By the end of the second or third day it is usual to find a considerable number of joints affected, so that the patient is already in much pain and great discomfort. The affected joints are swollen and red, and synovial effusions appear, especially in the knees, wrists and ankles. There is great variation in the extent and in the degree of the joint involvement in different cases. In a few instances less common joints share the inflammation: sterno-clavicular, vertebral, interphalangeal. The *fibrous tissues* suffer as well as the joints, and it is often apparent that this accounts for some, at least, of the stiffness and grave discomfort. The joint effusions never suppurate.

The *temperature* usually rises to 102° to 103° F. with the arthritis and synovial effusions, and the fever remits, or even intermits, so that the chart shows

an " irregular " curve. The pyrexia is peculiarly sensitive both to exacerbations in the disease (which are common), to relapses (which are also common) and to complications. Sweating is generally profuse, the sweat being of a peculiar " acid " smell. The *urine* is scanty and high coloured, and if the fever is marked there is usually a trace of albumin present; a deposit of urates, coloured brick-red by uro-erythrin, is a feature in most severe cases. As in most acute fevers, the *secretions* of the mouth and alimentary tract are lessened, leading to a heavily coated tongue, anorexia and constipation.

The *heart* is generally—some authorities believe always—affected, though the nature and the degree of the affection is variable. There are few, if any, cases in which careful examination from day to day does not reveal a slight degree of " softness " of the first sound of the heart, due, no doubt, to affection of the myocardium. The *pulse* is raised moderately in frequency (90 to 120), its volume is good but its tension is reduced. In more cases than not, probably, a soft systolic apex-bruit appears, not, however, necessarily indicating the occurrence of endocarditis. In about half of all cases there are reasons for concluding that *acute endocarditis* is present, as judged by the character of this bruit, its transmission towards the axilla, some evidence of enlargement of the heart and a rise in the temperature coincident with the appearance of the heart signs. This complication usually arises about the eighth to the tenth day.

The *blood* shows a considerable leucocytosis (15,000 to 30,000) and an acute " secondary " anæmia which is a constant feature of the disease and quickly reveals itself in the patient's facies. The erythrocyte sedimentation rate is increased during the active stages of the disease.

Aberrant Types.—*Subacute* attacks are common, especially in children (see p. 292) and in old rheumatic subjects. Their importance lies in the fact that all the time the heart may be suffering damage. Although this is less common in adults than in children, arthritic signs may be absent in cases of rheumatic endocarditis, as in rheumatic pericarditis.

Complications.—As already stated, about one-half of all cases develop some *heart* lesion. We have spoken of *myocarditis* and of *acute endocarditis*, and of the advent of the latter, should it arrive, about the end of the first week. The endocarditis is generally a valvulitis; most often mitral, less often aortic, but in some cases both mitral and aortic. *Pericarditis* is less common, though it may be the only manifestation of rheumatic infection; and pericardial effusion, especially of the massive sort, is nowadays quite uncommon. (For full accounts of these important cardiac complications, see special sections.)

Skin eruptions, though a specific feature of the infection, are not very common, except in children. The profuse sweating quite often leads to *sudamina*, and these, becoming inflamed, lead to *miliaria*. True *rheumatic erythemata* are much more common in the subacute cases than in the acute ones. *Purpuric* eruptions, again, are more often seen in aberrant types of the disease.

The only *pulmonary complication* of any consequence is pleurisy, and this is by no means common if we preserve the usual strict criteria of physical signs for its recognition, and omit " pleurodynia," in which condition the pain is more often intercostal than pleural. Indeed it may be said that, in the absence of pericarditis and of severe endocarditis, rheumatic pleurisy is

rare. Pneumonia also is unusual, but there is a condition of lung in severe rheumatic fever, again when complicated by grave endocardial, pericardial and pleural affections, which simulates it somewhat; the lung tissue is in a mixed state of congestion, collapse and œdema. A thin serous pleural exudate often accompanies this condition of the lung, and, no doubt, because of the associated pericarditis, it is more often found on the left than on the right side.

Hyperpyrexia was formerly a much dreaded, and not very uncommon, complication. It is now quite rare. There is, indeed, by some modern observers, doubt thrown upon the rheumatic nature of the cases described under this term. May they, for example, have been fulminating cases of septicæmia or meningitis? It is clear that no case could nowadays be termed rheumatic hyperpyrexia unless lumbar puncture and blood culture findings were proved to be negative. But the strongest points in favour of regarding some, at least, of the cases as having been rheumatic, and not meningitic or septicæmic, are (1) the very high degree to which the temperature rose (107° to 110° F.); and (2) the fact that in some of the cases, at least, the clinical picture was definitely that of rheumatic fever before the event, and when recovery occurred as the result of prompt treatment it was similar afterwards. The condition arises suddenly in most cases, though in a few there is a suspicious prodromal amelioration in the pain, sweating and general discomfort. The temperature rises rapidly to 106°, and unless checked by cold applications it may quickly reach 109° or 110° F. Before this stage is reached the patient has become tremulous and excited, then delirious and then semi-comatose, with a dusky lividity of the face and a failing pulse. Most of such cases are fatal. If prompt treatment succeeds in lowering the pyrexia it may need to be resorted to again in a few minutes or hours, since recurrence of the condition is to be expected.

Course.—Before the introduction of salicylates the course of rheumatic fever was, in the words of Sir Thomas Watson, "six weeks." Nowadays it is much shorter; 10 days to 3 weeks, if we include the joint swellings, though the fever is generally over in a shorter period than this when the treatment is prompt and thorough. If residual joint inflammations prolong the course of the disease it is important to look for contributory causes, and especially for septic foci. Recrudescences are very common, especially if full treatment be relaxed too early. Complications necessarily prolong the course of the disease.

Convalescence is often tedious, and the resultant anæmia and heart weakness warn the careful practitioner not to attempt to hurry it. Rheumatic fever patients are as liable to *relapses* as they are to recrudescences, and it is no uncommon thing to see a patient slip again into almost as bad a state as he originally was, including, it may be, painful swelling of the very same joints as were first affected. The great danger of these relapses lies in the risk of heart inflammations arising during the subsequent attacks, when perchance the patient escaped them at the first.

Prognosis.—Recovery is the rule in this disease; *death during a first attack is very uncommon.* When death occurs there is invariably serious carditis, especially myocarditis, and acute pulmonary complications (pleurisy and "rheumatic pneumonia") are usually present also. In rare cases, death occurs in a state of hyperpyrexia. When the attack supervenes upon old

rheumatic carditis, the prognosis is less good, heart failure being more easily induced. But in general it may be said that rheumatic fever is serious, not from its case mortality, but from its crippling effect upon the heart. *Residual conditions* are almost entirely cardiac injuries and chiefly scarred valves and auricular fibrillation; rarely some degree of limitation of movement in joints.

Rheumatic Fever in Children.—The disease is very common in children, in whom, however, the clinical picture as above described is apt to be departed from in several respects. (1) The arthritis is a less marked feature; it may be absent altogether, and even when it is a troublesome element in the case, the degree of pain is prone to be disproportionate to the amount of redness and swelling of the joints, and may be muscular rather than articular. (2) Skin eruptions are relatively more common—various erythemata especially, but also purpura. (3) *Rheumatic "nodules"* are almost confined to children, having the same age-incidence as *chorea* (see p. 1698). These are discrete lumps, varying in size from small peas to horse-beans; symmetrical in distribution, they are found in the scalp, along the margins of the scapulæ and bones of the forearm, about the knuckles and elbows, and, less often, in other situations. They are sometimes tender and painful. They come and go. Occasionally they are present in large numbers; the case is then most likely to be subacute in type and very tedious in its course: they are, therefore, of grave prognostic import as to the ultimate state of the heart, being indicative of a "smouldering" endocarditis. They consist of elements approximating to the "essential" lesion of the disease to which reference has been already made. (4) But the most important difference observable between the disease in children and in adults is the fact that in the former the process is not seldom subacute in its onset and course, and for this reason frequently overlooked for a time. Add to this fact that the tendency to heart involvement in these subacute attacks is no less than in the more acute and more highly febrile bouts, and it is obvious that the recognition of this state of things is of the utmost importance. Unfortunately a large number of cases of subacute rheumatic endocarditis must needs arise without the possibility of prevention, but it is probable that a large number might also be prevented, or considerably modified, by prompt treatment of the subacute rheumatism in childhood which causes the injury. These attacks of subacute rheumatism are sometimes characterised by intercostal pain, sometimes by abdominal pain, sometimes by pain in the legs without special reference to the joints. There seems no doubt that so-called "growing pains" are often rheumatic in nature. In any child so affected the heart should be examined critically, and from time to time. The presence of sore throat, of acid sweats, of one of the erythemata, in conjunction with the above-named pains, should determine a decision to treat the child as suffering from the rheumatic process. The presence of nodules is decisive in a doubtful case.

Diagnosis.—Cases of the fully developed disease do not often lead to difficulty in diagnosis, given ordinary care on the part of the practitioner. A few diseases, however, require mention. (1) *Pyæmia* due to coccal infection may lead to some confusion, and the following differential points are worthy of notice. In septicæmia, when there is arthritis, the latter is usually constant in one or two joints, not fugitive and involving many as in rheumatic fever. Moreover, the joint changes tend to suppuration and permanent

destruction of the joint structures. Blood cultures and joint-puncture fluids are not infrequently positive in pyæmia, whereas they are constantly negative in acute rheumatism. Rigors are common in pyæmia; in rheumatic fever they do not occur. If endocarditis complicates pyæmia, the heart infection is likely to lead to embolism, a condition not found in rheumatic fever. But between this type of streptococcal septicæmia and rheumatic fever all grades of cases are seen.

(2) In children *acute osteomyelitis* may be mistaken for rheumatism; rarely does the converse error arise. But the disease-process is nearly always much more severe, the temperature being much higher and showing greater oscillations. The painful part is generally the lower end of the femur or tibia, and careful examination reveals it to be epiphysial rather than arthritic. As in pyæmia, to which type of infection the disease really belongs, blood cultures are usually positive (*Staphylococcus aureus*).

(3) *Gonorrhœal arthritis* is not usually so acute a disease, nor is the patient often so ill as in rheumatic fever. The joints are fewer in number, and, as in pyæmia, the course of the individual involvement is much longer. The inflammation, too, affects peri-articular as well as articular structures; not seldom it involves adjacent tendon sheaths also. Gonococci may be isolated from the joint effusions. Although the presence of a urethral or vaginal discharge makes a diagnosis of gonorrhœal arthritis likely it does not prove it; and it must be remembered that the discharge not infrequently ceases temporarily with the onset of the arthritis.

(4) *Acute osteo-arthritis* is a rare disease, but when it occurs it produces a clinical picture that is probably closer to rheumatic fever than does any other disease-process. The patient is more often a woman than a man, and is generally older (30 to 60) than is the average case of rheumatic fever. The failure of salicylates in full doses to reduce the temperature, and to affect beneficially the course of the joint condition, should always raise doubts as to the nature of a supposed case of rheumatic fever. This differential point applies equally to diseases 1 to 3.

(5) *Gout*, when present in the acute arthritic form, may be mistaken for rheumatic fever; rarely does the converse happen. The patient is generally a man over 40 years of age; the number of joints involved is rarely more than two; the skin over these is generally dusky red in hue, and shining; there is often definite soft œdema. *The presence of severe pain when the affected joints are at rest is much in favour of gout.* The degree of fever is usually much less in proportion to the degree of joint inflammation than is the case in rheumatic fever. The presence of tophi may be taken as confirmatory of gout in a doubtful case.

(6) *Meningococcal meningitis with arthritis* rarely simulates rheumatic fever, but one of the writers (H.) has seen such a case, in which there were pungent acid sweats and purpura, and the resemblance to a case of severe rheumatic fever was for a time very close indeed.

Treatment.—(1) *General.*—With as much promptness as possible, the patient is put to bed, and is kept there until it is certain that the heart is unaffected, or, if affected, until it is certain that the inflammatory process has ceased to be active (see p. 917). The bed should be chosen carefully; narrow enough to admit of easy nursing, and having a soft but firm mattress. The patient lies in blankets with a long flannel garment opening down the front,

and having sleeves to the wrists; this garment is changed as frequently as need be, according to the degree of sweating. The position of the patient is one of recumbency, with the affected joints supported in a position of maximum comfort. Movements of the limbs are generally best carried out by the patient's own efforts, and in all except severe cases, and where the heart is affected, movements of the body as a whole may also well be left to the patient. The basis of the *diet* should be milk diluted with water or alkaline mineral waters, and so long as the fever remains a marked feature of the case nothing should be added to this unless it be whey, peptonised milk or barley water. Abundance of fluids should be allowed, for a great deal of fluid is lost to the body through the profuse sweats. Imperial drink is very useful. As the fever declines, there may be added to the milk, oatmeal, vegetable soups and chocolate. Meat should be reserved for convalescence, and even then should be given very sparingly. Tea and coffee are best omitted altogether. Fruit is disallowed. Aperients are given as necessary.

In the matter of *drugs* there is a consensus of opinion that salicylic preparations deserve the name of specific remedies. They control the arthritis, cause the fever to decline, and cut short the course of the disease-process. They also lessen the tendency to relapses, and often render these abortive when they threaten. It may be quite true that they do not prevent the occurrence of endocarditis, nor affect this inflammatory process beneficially when once established, but a remedy which cuts short the course of a disease must necessarily, in an indirect measure, act as a deterrent in respect of its complications. Thus, by prompt exhibition of salicylates an attack of rheumatic fever may be almost resolved by the eighth day, at about which period in the disease acute endocarditis is specially liable to develop. Certain it is that pericarditis, and in particular pericarditis with liquid effusion, is much less common nowadays than it was in the pre-salicylic days; so also is hyperpyrexia; and it is unlikely, in view of the more general features of rheumatic fever and its incidence, that the disease-process has itself undergone any change during the past 50 years which is likely to account for these facts. The preparation of the drug which has become most popular and deservedly so, is sodium salicylate. *It should be given in sufficient quantities, and the doses should be distributed as evenly throughout the 24 hours as is compatible with securing good sleep for the patient.* At the onset of treatment of an acute case in an adult, 20 grains should be given every 2 hours during the day, and every 4 hours during the night (200 grains in the 24 hours). Many authorities advise that twice these amounts of sodium bicarbonate be added to the salicylate to prevent acidosis; in the writers' opinion half the quantity of bicarbonate, *i.e.* 100 grains in the 24 hours, is sufficient and less likely to induce vomiting. If a child vomits a dose of salicylate, another given immediately will probably be retained. As the fever and pain diminish, these quantities may be given somewhat less frequently, a note being kept on the temperature chart of the total amount given in the 24 hours. In a child of 12 years or so, half these quantities may be given. If no amelioration follows these doses in 48 hours they should be increased by 50 per cent. (150 grains in 24 hours). If an exacerbation occurs, or a relapse threatens, after the dosage has been reduced, it should be at once adjusted to its original level. The drug is not unpleasant to take, and its taste is easily masked by liquorice water as a vehicle. Quite apart from the inestimable value of giving adequate

doses so as to gain time, there is an additional value in this procedure from the point of view of diagnosis, for a *patient suffering from acute arthritis with fever, who is not considerably better after* 48 *hours' treatment by full doses of salicylates almost certainly is not suffering from rheumatic fever.* The diagnosis in these circumstances should be at once revised. It will be found that the great majority of patients tolerate the above specified doses of salicylates without ill-effects. In the few instances in which it produces vomiting, or intense depression, or delirium, or coma, or hæmaturia—symptoms thought from time to time to be toxic effects of the drug– either aspirin in similar doses, or salicin in somewhat larger doses, may be substituted. But care must be taken in deciding that such symptoms are really due to the salicylate and are not manifestations of the rheumatic poison. Modern synthetic preparations of sodium salicylate are fairly free from the contaminations which were formerly rather common. In the early stage of the disease it may be necessary to adopt more rapid palliative measures for the *severe pain*, especially if this prevents sleep. Nothing is better than opium, either as pulv. ipecac. et opii, grs. 10, or pil. saponis co., grs. 5. It is better to avoid phenazone and phenacetin. The treatment of heart complications is discussed elsewhere (Sect. XIII.). Against the occurrence of these complications, apart from the value of early and liberal use of salicylates, we seem to be powerless. But some authors attach importance to small blisters applied to the præcordium early in the disease.

Hyperpyrexia is met by prompt application of the cold pack, with volatile stimulants; the pack may need frequent renewal, and in extreme cases the water used for it must be iced. The most constant vigilance is necessary in such cases, which, as already stated, are happily rare nowadays.

In the treatment of prolonged cases of the disease the writers believe iodine (preferably not in the form of the potassium salt) to be useful, and especially so in cases complicated by serous inflammations, whether cardiac or other. Such experimental treatment of these prolonged cases by sera and vaccines as the writers have observed has not led them to employ either in any routine fashion. "Channels of entry" should, in protracted cases, be adequately dealt with as in (4).

(2) *Local.*—The position of optimum comfort of the affected joints has been already referred to. The use of splints for fixing the joints often gives relief. In the milder cases it suffices to wrap the joints in cotton-wool and bandage them lightly. In the more severe cases a lotion of tinct. opii, 1 fl. oz.; glycerin, 2 fl. oz.; water, 12 fl. oz.; sod. carb. to saturation, used hot, gives as much relief as anything. An alternative is one of the preparations of methyl salicylate, used freely, but without rubbing. Aspiration of the effusion is scarcely ever needed; its indication, indeed, should raise doubts as to the diagnosis.

(3) *During convalescence.*—Convalescence is generally slow, and should not be hurried. If the heart has suffered by direct inflammation, the recumbent position must be prolonged until it is certain that quiescence is established in that respect; this usually means from 4 to 6 weeks after the subsidence of the fever. The disastrous effects of attempting to hasten convalescence in such cases are to be seen amongst patients who have been treated in institutions which advertise a false efficiency by reporting a "shorter average stay in hospital" than is the case in sister institutions.

The transition from strict recumbency to a sitting posture should occupy a whole week, by the gradual addition of pillows, and the further return to ordinary active life should be graduated with care.

Tonic preparations, such as quinine and hypophosphites, are useful, but the tradition that iron is not well tolerated until late in convalescence—though the state of anæmia seems to indicate it—is confirmed by experience. Diet during convalescence has already been referred to. Massage and passive movements of the affected joints may be begun so soon as the inflammation has completely subsided.

(4) *Preventive treatment.*—Failing exact knowledge of the essential causative agent in rheumatic fever, no effective mode of prevention can at present be devised. But if there be a doubtful "channel of entry" present in any case, this should be dealt with in some radical fashion, in any patient who has had an attack, or is a member of a susceptible family. "Septic" tonsils should be enucleated, and an appendix which has at any time shown signs of inflammation should be removed.

ERYTHEMA NODOSUM

Ætiology.—Although this disease is a fairly definite and easily recognisable clinical entity, it is still uncertain where it should be placed, when considered in relation to nosology or to ætiology. Formerly the favoured view was that the disease is a manifestation of acute rheumatism. Since, however, it is less often than not associated with the more definite criteria of acute rheumatism (arthritis, endo- and pericarditis), since it rarely recurs in the same patient, and since treatment by salicylates in full doses does not cut short its course, it is very doubtful if it should be regarded as a true rheumatic affection. A more recent view is that the disease is intimately related to tubercle: the lesions being toxic rather than actual areas of infection: the isolation of tubercle bacilli from them, originally reported, has not been confirmed. Alternative views are not lacking. By some erythema nodosum is thought to be an acute specific disease due to an unknown virus. Collis suggests that it is a type of hyper-reactive tissue response to different bacterial allergens and that the allergens responsible for erythema nodosum in London are commonly tuberculin and the toxin of hæmolytic streptococci.

It occurs more often in females than in males (according to Mackenzie, in the proportion of five to one), and the majority of cases are found between the ages of 10 and 30 years. There is no seasonal incidence. In the experience of the writer it is much more common in hospital than in private practice; this and some other observations suggest that bad feeding or insanitary conditions may contribute to the incidence of the affection.

Pathology.—There has been demonstrated a widespread arteriolitis in the subcutaneous fat, resolving without suppuration or residual fibrosis.

Symptoms.—The symptoms consist of: (i) the local lesions, and (ii) certain constitutional changes.

(i) The local lesions are bilateral and occur chiefly upon the lower limbs; indeed, in the great majority of the cases they are confined to these. When they appear on the arms they are most often found only in this situation, the patient is more often than not an adult, and the general symptoms are

less like rheumatic manifestations than is the case in the more common variety of the disease. The lesions are round or oval swellings, usually confined to the extensor aspect of the limbs, affecting the shin regions chiefly, and varying in size from a large pea to half an orange. There may be two or three only on each leg, or, in severe cases, the greater part of the extensor surface may be covered by them. They involve the subcutaneous tissue as well as the skin. They are very tender to touch. On their first appearance they are deep red in colour, later they become purple in hue, and still later they often show a definite ecchymotic appearance—giving rise to the name dermatitis contusiformis. In bad cases there is a good deal of associated œdema of the surrounding tissues.

(ii) The general symptoms include a mild grade of fever (not constantly present), joint pains, malaise and sore throat. But many cases occur in which the local skin condition, with pain and tenderness, covers the whole of the symptomatology. Constipation is common, and is sometimes severe: in a case of the writer's, in a young man, there had been no action of the bowels for 10 days, and the patient had suffered from constipation all his life.

The course of the disease is from 2 to 3 weeks, but some mild cases get well, if treated, within a week.

Diagnosis.—The diagnosis is not difficult. Radcliffe-Crocker says that the lesions may be mistaken for syphilitic nodes: the distinction is made by the presence of other signs of syphilis, by the fact that the pains in the latter disease precede the appearance of the node through the skin, and by the lack of response to treatment by iodide of potassium. The lesions of Bazin's disease, though they occur on the legs much more than on the arms (as in erythema nodosum), though the sex and age are the same and though the association with tuberculosis is definite, are chronic and relapsing in character, and ulceration usually occurs.

Treatment.—Rest in bed, with the legs elevated, and general hygienic conditions, suffice to bring about spontaneous recovery in all cases. No drug has credit for cutting short the course of the disease. Recovery has been found to be quite as rapid when the patient is treated by small doses of hydrarg. c. cretâ with saline aperients, as when she is given full doses of sodium salicylate. As a local application lead lotion is perhaps the most soothing.

EPIDEMIC MYALGIA

Synonyms.—Epidemic or Infectious Pleurodynia; Bornholm disease; Epidemic diaphragmatic spasm; Devil's grip.

Definition.—An acute infectious epidemic disease of short duration characterised by sudden onset of pain in the upper abdomen and lower thorax, pyrexia, sweating, and a tendency to relapse.

Ætiology.—The disease occurs usually in the late summer and autumn; it mainly affects children under 15 years of age. The exciting cause is unknown; infection appears to be spread by direct contact only, the incubation period being 2 to 5 days; the patient remains infective so long as the pain persists. One attack may not confer lasting immunity.

Pathology.—Nothing is known of the pathology. No abnormality has

been detected in those cases in which an exploratory laparotomy has been performed owing to mistaken diagnosis.

Clinical Features.—The onset is sudden, with acute spasmodic pain in the region of the xiphisternum and the attachment of the diaphragm, perhaps more on one side than the other. The pain leads to shallow rapid respiration, and is intensified by deep breathing, by yawning, sneezing or cough; a spasm during a period of quiescence may be induced by laughing. In adults, pain may also be complained of in the neck and extremities, and there may be some frontal headache. The temperature rises rapidly, perhaps to 104° F., and subsides within 24 hours. There is a marked tendency to a return of pain and pyrexia during 3 or 4 days, and the second attack may be the more severe. Profuse sweats are common, anorexia the rule, while vomiting and diarrhœa are seldom met with.

There are no physical signs, other than in the character of the respiration, of involvement of the pleura, lung or peritoneum. There may be some cutaneous hyperæsthesia and tenderness on pressure in the painful area, especially in the epigastrium. In some cases a leucocytosis occurs, and eosinophilia has been reported during convalescence. No abnormality has been detected on X-ray examination.

Complications are infrequent. Conjunctivitis, catarrh of the upper respiratory tract or orchitis have been reported in certain epidemics. There are no sequelæ. Prognosis is good.

Treatment.—The patient should be isolated, and remain in bed until 48 hours after the pyrexia and pain have subsided. Ordinary methods for the relief of pain are indicated.

HORDER.
A. E. GOW.

PINK DISEASE

Synonyms.—Infantile Acrodynia; Erythœdema; Vegetative Neurosis.

History.—The disease was first accurately described by Swift (Australia) in 1914, but Selter (Germany) had reported similar cases in 1903, and Swift records that he certainly saw examples of the disease when he was a resident at the Hospital for Sick Children, Great Ormond Street, in 1885. Feer (Zurich) is generally accepted in Europe as having described cases about the same time as Swift.

Ætiology.—The clinical syndrome is generally ascribed to the effects of a widely diffused toxin which shows a predilection for the vegetative nervous system. It frequently follows an acute infection of the upper respiratory tract and less often gastro-enteritis, either affording a possible portal of entry of a virus. Although not obviously infectious from case to case, small epidemics in localised areas have occurred in various parts of the world. This and a tendency to a seasonal incidence in spring and autumn offer obvious analogies with acute anterior poliomyelitis; and Mayerhofer has described cases following this disease. Another theory favours a vitamin or other deficiency, but usually affected children have been well fed. Hypersensitivity to sunlight has also been put forward, but claims to a cure by the exclusion of sunlight in England are balanced by equally well supported claims to great benefit by exposure to sunshine in Australia. The balance of

present evidence favours a virus. The disease occurs more especially in the temperate zones, affects the sexes equally and is almost limited to the period covered by the time of the primary dentition.

Pathology.—Apart from various findings due to secondary infections, the specific morbid pathology of the disease is said to include minor microscopical changes in medulla, cord and peripheral nerves. These consist of round-celled infiltration, demyelinisation and œdema. Some authorities maintain that even these changes are due to a non-specific terminal infection, or to secondary nutritional depletion.

Symptoms.—After a vague febrile onset, as intimated above, the infant fails to recover its previous vigour, and remains essentially miserable, with insomnia, muscular hypotonia, increasing loss of appetite and usually loss of weight. After a week or so some degree of stomatitis is commonly found, the child dribbles a lot, and just when the whole picture has been confidently ascribed to the effects of dentition the characteristic rash makes its appearance. This consists of three main features: a sweat rash, which may be present all over the trunk and proximal portions of the limbs; a curious "raw beef," puffy, non-pitting œdema of the hands, feet and frequently of the nose; and eventually various degrees of furunculosis and pyodermia. The condition of the mouth deteriorates, teeth may be shed (and swallowed), photophobia is often marked, and the child "burrows" in misery in the bedclothes, constantly scratching and rubbing the hands and feet together. In severe cases the fingers and toes may be seriously bitten and the hair plucked out. Perspiration of a cold, clammy type is present and produces a "mousy" odour. Wasting and hypotonia become extreme, the child makes no effort to stand or walk, and prolapse of the rectum may occur. Signs of affection of the nervous system are shown by a persistent tachycardia—which is constant and varies in degree according to the severity and state of the disease—the tendon reflexes are frequently diminished or lost, and it may be possible to demonstrate a diminished sensitivity to pin-prick. The disease is usually afebrile save for the effects of complications, the blood pressure is said to be raised, although the determination of this is a matter of some difficulty, and there is frequently a leucocytosis.

Complications.—The upper respiratory tract infection may spread to affect the ears and, more seriously, to produce broncho-pneumonia, which is always a menace because of the risk of aspiration with an infected mouth. Pyelitis is not uncommon. Various local infections of the skin are almost invariable in a case of ordinary severity. Sequelæ, however, are unknown and relapses seldom occur.

Course.—The whole clinical picture may be spread over three to nine months, with some variation in the severity of the symptoms.

Diagnosis.—There is no mistaking the disease once it is fully developed, and it obviously should be suspected whenever a young child appears to be seriously miserable for weeks at a time. Cases have been described with most of the classical symptoms, but without the rash or other skin changes. Tachycardia occurs in all cases, and unless the pulse rate is 140 or more a diagnosis of pink disease should not be made with confidence.

Prognosis.—In the absence of serious complications this is invariably good, and one attack confers immunity. Death is usually the result of some serious complication but occasionally is sudden after a period of increasing

rate and irregularity of the pulse. It is suggested that in such cases the end is due to ventricular fibrillation.

Treatment.—Since the exact causation is unknown, preventive measures are impossible, and most of the treatment has perforce to be symptomatic. Good nursing is essential but hospitalisation is undesirable; a well-trained nurse in the home is indicated as the patient's mother is almost invariably worn out. If weather permits the child's cot should be in the open air as much as possible, day and night. Silk or cotton clothing, frequently changed, is best, the eyes should be protected from glare, and some restraint may be necessary to prevent quite serious self-infliction of damage to the skin. The diet should be adequate, well-balanced, mostly liquid and offered cold, frequently and in small quantities. The troublesome anorexia can only be dealt with by skilful nursing. Deference to the deficiency theory of origin would indicate the administration of vitamin concentrates A, B, C and D, raw liver, and some yeast preparation, such as yestamin. Good results have been claimed for the injection of vitamin B_1 in massive doses, such as 1000 international units once a week. This has the merit of being a convenient way of treating an out-patient at a hospital. Bellergal (one to three tablets daily for several days) is believed to counteract the effects of the disease upon the sympathetic nervous system. Some sedative is essential and a mixture of chloral and bromide, according to the age, is probably the most suitable and should be used freely. For the skin a tepid bath (to which disinfectant, such as liq. hydrarg. perchlor., may well be added) once or twice daily, followed by a methylated spirit rub and copious powdering with a fine and talc (not starch) powder, will help to promote comfort. The irritation may be slightly allayed by calamine lotion or the use of menthol in paraffin (1 per cent.) dabbed on at night. The mouth requires great care. Giving the child swabs soaked in hydrogen peroxide may be recommended, and actual inflammatory lesions should be dabbed with methyl violet solution (1 per cent. in water). During convalescence an iron tonic and a change to the seaside help to promote complete cure.

ALAN MONCRIEFF.

SECTION III

TROPICAL DISEASES OF DOUBTFUL OR UNKNOWN NATURE

LATAH

Definition.—A form of cerebral neurosis, in which the patient makes involuntary movements and incoherently utters sounds or words (Scheube).

Ætiology.—The condition has been found in Java, the Philippines, Burma and Siam, and natives are affected, principally young women. Heredity may play a part, but no exciting cause is known.

Pathology.—There are no records of any post-mortem examinations.

Symptoms.—The movements and incoherent sounds are involuntary, the patient being unable to restrain them. The reflexes may be increased, and people affected take fright easily.

Diagnosis.—The disease must be distinguished from ordinary mental and nervous disorders.

Prognosis.—The disease may persist for years, and appears to be incurable.

Treatment.—None is known. Treatment by suggestion might be tried.

KUBISAGARI

Definition.—A disease associated with dimness of sight, diplopia and paresis of the cervical muscles (Miura).

Ætiology.—The condition is found endemically in parts of Japan. It attacks the agricultural natives of any age or sex, and house epidemics have been recorded. The cause is unknown.

Pathology.—This has not been established.

Symptoms.—Depression is usually present, followed by dimness of vision, often accompanied by ptosis of the eyelids; paresis of the cervical muscles, muscles of the trunk, etc., are also common. Owing to the implication of the cervical muscles the head hangs down, whence the name of the disease. The symptoms intermit, intervals of freedom alternating with new attacks.

Diagnosis.—It must be distinguished from other forms of paralysis.

Prognosis.—The disease is said never to end fatally.

Treatment.—Miura recommends potassium iodide and arsenic.

AINHUM

Definition.—A disease of the toes, characterised by a ring-shaped constriction, which finally causes amputation of the toe affected.

Ætiology.—The disease is principally found on the West Coast of Africa, but it has also been seen in Brazil, British Guiana, the West Indies, the southern states of the U.S.A. and in India. Negroes and Hindoos are attacked, adult males being especially affected. The cause is obscure. A trophic origin has been suggested; also injuries, such as cuts from grass, jiggers, etc.

Pathology.—The constricting ring is formed of fibrous tissue. An increase in the adipose tissue of the part has been noted by some, a thickening of the epidermis by others. The underlying bone may undergo absorption. Natives are very prone to fibrous tissue formation, *e.g.* keloid.

Symptoms.—The little toe is most usually affected. The disease commences by a groove or furrow, which first appears in the digito-plantar fold; this gradually deepens and spreads round the portion of the toe distal to the swelling. The change advances until the band is so narrow that the toe hangs by a thin pedicle. Finally the part may drop off spontaneously, be torn off, or be purposely cut off by the patient. The course of the malady is slow—usually several years.

Prognosis.—There is no danger to life: the disease may last 10 years.

Treatment.—Da Silva proposes vertical incisions through the constricting band in the early stages. Later, surgical amputation is advisable.

BIG HEEL

Synonym.—Endemic hypertrophy of the os calcis.

Definition.—A peculiar hypertrophic condition of the os calcis.

Ætiology.—This has not yet been established. The condition occurs in natives of the West Coast of Africa, chiefly on the Gold Coast. It is possibly connected with yaws.

Symptoms.—The disease is ushered in with fever, followed by pain and tenderness in the heel, with swelling of the os calcis of one or both feet. Cold and damp are apt to produce an increase in the symptoms, and walking is hindered. The condition may become chronic, permanent thickening of the bone resulting.

Treatment.—If the enlargement be excessive, removal of some of the hypertrophic bone may be attempted.

CHAPPA

Definition.—A peculiar affection of the joints associated with nodules in the subcutaneous tissues, which finally ulcerate.

Ætiology.—The disease was described by Read in Southern Nigerai.

Natives only are attacked as far as is known. The causative agent has eluded detection.

Pathology.—This is not yet entirely known. Nodules, as large as a pigeon's egg, form in the subcutaneous tissues, with ultimately complete destruction of the joints—the bones are also attacked.

Symptoms.—The disease, according to Read, begins with severe pains in the limbs, muscles and joints. After a time, nodules appear in the tissues, and the skin over them breaks down with resulting ulcer formation. The ulcers have no tendency to heal, but may remain for years.

Diagnosis.—The disease has to be distinguished from onchocerca nodules, tropical ulcer and yaws. Possibly it may be a late stage of the latter disease.

Prognosis.—This is bad.

Treatment.—Scraping is indicated. Arsphenamine or its derivatives may be administered, but no definite specific remedy is known.

ONYALAI

Synonyms.—Chilopa ; Kafindo.

Definition.—An acute disease affecting natives of Central Africa, characterised by blood-filled vesicles inside the mouth and involving other mucous surfaces, hæmaturia and the passage of blood per rectum.

Ætiology.—The disease may affect natives of any age or either sex, and is met with in Portuguese West Africa, along the Lualaba River, in the Belgian Congo, in Bukoba, East Africa, and in Northern Rhodesia. Gilkes believes it to be a vitamin deficiency. Blackie has recently suggested that onyalai is an acute form of essential thrombocytopenia due to defective maturation of the megakaryocytes of the marrow with an associated modification of the endothelium of the capillaries as a contributory cause in the production of the bullæ.

Pathology.—The vesicles are umbilicated, oval or circular, and about the size of a pea. They contain fluid and coagulated blood, and are trabeculated. Hæmorrhages are scattered throughout the organs, serous membranes and skin.

Symptoms.—The disease is usually ushered in by headache, vague pains in the chest and fever. After some time an eruption of small blebs and vesicles appears on the buccal mucosa and hard palate, and blood is discharged from the nose and mouth. The tongue and parotid glands become swollen. In severe cases bleeding begins from the bladder, rectum and intestines and anæmia develops. Hæmaturia appears rarer in Rhodesian than in West African cases. The temperature may rise to 103° or 104° F., though in fatal cases it may remain subnormal. Relapses are not infrequent.

Diagnosis.—This has to be made from purpura, pemphigus, smallpox and viper bites. The gums are not swollen, nor are the joints involved.

Prognosis.—Natives dread the disease. Gilkes (1934) gives 13 deaths out of 53 cases, and in a series of 17 cases seen by himself, 8 were fatal in a few days and 3 died later from relapses.

Treatment.—A high vitamin diet, including green vegetables, fruit, orange juice, fresh milk and marmite, should be given. Intramuscular injections of whole blood cure the majority of cases. Blood transfusion and iron medication may sometimes be advisable.

CHIUFA

Synonyms.—Chinkumbi; Kanyemba.

Definition.—An acute inflammation of the rectum, commencing at the anus and extending upwards, later involving the colon.

Ætiology.—The disease, which occurs especially in the hot weather and rains, has been described by Gilkes (1934) in natives of the Lunsenfwa and Luangwa Valleys in Northern Rhodesia. The cause is unknown.

Pathology.—No post-mortem examinations have so far been possible.

Symptoms.—The onset is sudden, and the disease runs an acute course which may end fatally in a few days. A white powdery condition appears round the anus, and in females the vulva and vagina may also be implicated. Later the skin becomes reddened and hard, the sphincters relax, and the anus opens out revealing a dilated and acutely inflamed rectum. When the disease involves the colon, diarrhœa and vomiting may occur. Anorexia, rapid loss of weight, and involuntary passage of fæces and urine follow.

Diagnosis.—The disease resembles epidemic gangrenous rectitis, which occurs in tropical South America and may be related to it, though gangrene is not met with.

Prognosis.—This is bad, but recovery may occur.

Treatment.—Only native remedies, so far, have been employed, a powder made from bark and leaves being blown into the rectum. These probably owe any efficacy they possess to their tannic acid content.

MOSSY FOOT

Definition.—An infective disease resulting in a papillomatous condition of the feet and legs, seen especially in natives inhabiting the Amazon valley.

Ætiology.—The disease originally met with in Brazil by Thomas has also been described in Honduras, Costa Rica and Guatemala. Some attribute it to the fungus, *Phialophora verrucosa*, others regard it as a form of tuberculosis cutis. The causative agent is not known with certainty.

Pathology.—Vascular granulomatous warty masses are found in the feet and legs, perhaps covered by yellow crusts. Sinuses do not occur.

Symptoms.—The condition starts as a vesicle on the dorsum of the foot, extending upward until the whole of its surface and possibly also the leg are covered with very vascular and painful warty masses: the sole is not affected. Elephantoid legs are sometimes attacked.

Diagnosis.—The condition has to be distinguished from verruga peruviana, Madura foot and yaws

Treatment.—The cautery is probably the best treatment. X-rays may be tried.

N. Hamilton Fairley.

SECTION IV

DISEASES DUE TO METAZOA

A. DISEASES DUE TO TREMATODES OR FLUKES (DISTOMIASIS)

PARAMPHISTOMIASIS

Definition– An invasion of man with amphistome flukes of the family *Paramphistomidæ*. Two of these parasites are known. *Watsonius watsoni* (*Cladorchis watsoni*).—L. 8 to 10 mm. × 4 to 5 mm.; Ova, 120 to 130 × 75 to 80 μ. The parasite has a reddish-yellow colour when fresh and inhabits the duodenum and upper part of the small intestine. *Gastrodiscus hominis*.—L. 5 to 8 mm. × 3 to 4 mm.; Ova, 150 × 72 μ. The parasite has a large posterior disc by which it attaches itself to the mucous membrane of the bowel; it occurs in the cæcum and colon.

Symptoms.—Diarrhœa, with loose bilious stools in the case of the former parasite, and intestinal disturbances with diarrhœa in the latter. The eggs of both parasites are found in the fæces.

Treatment.—Carbon tetrachloride (3 c.c.) is probably specific.

FASCIOLIASIS

Definition.– An invasion of man and other animals with flukes of the family *Fasciolidæ*. Several of these are known.

(1) *Fasciola hepatica* (*Distoma hepaticum*), the common liver fluke inhabiting the bile ducts of sheep and other mammals.—L. 20 to 30 mm. × 8 to 13 mm. The ova are operculated and oval, measuring 130 to 145 × 70 to 90 μ. From them miracidia emerge which develop into sporo-cysts, rediæ and cercariæ in snails of the species *Limnæa truncatula*; later the cercariæ encyst on grass stems and are subsequently eaten.

Symptoms.—Man is occasionally infected; light infections may be discovered accidentally during stool examinations, while severe cases may succumb to secondary cholangitis and liver abscess. In sheep the disease produces liver rot, which may be fatal.

Treatment.—Filix-mas administered in milk or capsules in a dose of 0·1 c.c. per kilo. and repeated in 24 hours will destroy adult, but not young, flukes. Good results are reported following a course of emetine injections. Carbon tetrachloride is effective in sheep and has been favourably reported

on in human cases; it is, however, a dangerous drug where there is calcium deficiency. Success has folowed the oral administration of large doses of magnesium sulphate combined with intravenous injections of stibosan.

(2) *Fasciolopsis buski* (*Distoma crassum*)—L. 30 to 70 mm. × 12 to 14 mm; Ova, 120 to 130 × 77 to 80 μ.—This giant fluke is found in China, Borneo, Malaya, Assam, Bengal and other regions in the East: it inhabits the small intestine, particularly the duodenum, producing focal lesions. The immature eggs are voided in the fæces, the miracidium matures in 3 to 7 weeks and escapes through the operculum. It enters certain snails (*Planorbis cœnosus*, *Segmentina nitidella*, etc.) and develops into sporocysts and rediæ which generate cercariæ: the latter encyst on water plants—water caltrop and water chestnut—man becoming infected by eating the corms. The cercariæ excyst in the duodenum and mature.

Synonym.—The incubation period is 3 months. Initial symptoms include hypogastric pain, acid dyspepsia relieved by food, and diarrhœa. Later, asthenia, œdema of the face and extremities, ascites and dry, harsh skin develop.

Diagnosis.—The condition may simulate gastric ulcer or typhoid, and is diagnosed by finding the ova in the stools.

Treatment.—PROPHYLACTIC.—Consists of cooking water caltrops and water chestnuts and sterilisation of night soil.

CURATIVE.—Carbon tetrachloride (3 c.c.), hexyl-resorcinol (1 g.) and beta-naphthol (5–10 grains) are specifics. Thymol or eucalyptus mixture has also been extensively used.

PARAGONIMIASIS

Paragonimus westermani (*Distoma westermani*; *D. ringeri*)

Definition. An invasion of the pulmonary tissues by the lung fluke, a member of the family *Troglotrematidæ*.

Ætiology.—Paragonimiasis occurs endemically in the Far East, especially Formosa, Japan, Korea and China. The adult flukes (7·5 to 12 mm. × 4 to 6 mm.) form cysts in the lung, where the broad, oval, immature, operculated ova (80 to 118 × 50 to 70 μ) escape via the bronchi and appear in the rusty brown sputum: they are also found in the fæces (40 per cent.). After attaining maturity the miracidium emerges, and invades a melaniid snail, especially *Melania libertina*, where it forms sporocysts, rediæ and, later cercariæ which encyst in the gills, liver and muscles of certain fresh-water crabs or cray fish—*Potamon obtusipes*, etc. If eaten by man the adolescaria emerges in the duodenum and migrates via the peritoneal cavity and diaphragm into the lung.

Pathology.—Host reaction results in cyst formation around the fluke, which generally communicates with adjacent bronchi, into which the eggs and anchovy-sauce cyst content are discharged. Pulmonary lesions consist of fibrosis, cystic dilatation of the bronchi, pseudo-pneumonia and tubercle-like abscesses. Similar cysts may involve the intestinal mucosa, bile ducts, peritoneum, pleura, brain, spleen and liver.

Symptoms.—These are divided as follows: (1) *General*, which include adenitis and skin ulcerations; (2) *Thoracic*, characterised by cough and

hæmoptysis with physical signs of broncho-pneumonia, pleural effusions or bronchiectasis ; (3) *Abdominal*, with involvement of the liver, spleen, pancreas or intestine : if the latter, there is diarrhœa with eggs in the fæces ; (4) *Cerebral*, with Jacksonian epilepsy, hemiplegia, monoplegia, aphasia and eye symptoms. Headaches, loss of memory and insomnia may be present.

Diagnosis.—This is made by finding ova in the sputum or fæces. The complement-fixation reaction may be of assistance : eosinophilia is also present.

Prognosis.—Brain cases are fatal, and the outlook is bad in all severe infections.

Treatment.—Abstinence from eating raw fresh-water crab or cray fish prevents the disease. Emetine and tartar emetic temporarily relieve pulmonary symptoms, but cures are doubtful (Faust).

CLONORCHIASIS

Definition.—An invasion of the bile ducts of man and other mammals with trematode parasites of the family *Opisthorchidæ*, occurring in Japan, Korea, China, etc.

Ætiology.—*Clonorchis sinensis* (*Distoma sinense ; Opisthorchis sinensis*, etc.) is a spatulate fluke, measuring 10 to 20 mm. × 2 to 5 mm. Its yellowish-brown ova are oval, possess a well-marked operculum, and measure from 27·3 to 35·1 × 11·7 to 19·5 μ. Viable eggs are ingested by certain bithyniid snails (*Parafossarulus striatulus*, *Bithynia fuchsiana*), and the miracidia, penetrating the soft parts, form sporocysts, rediæ and finally cercariæ, which escape, and encyst in the flesh of certain freshwater fish of the family *Percidæ*, *Gobiidæ* and *Anabantidæ*. When the mammalian host eats infected fish the adolescaria escapes in the duodenum and directly invades the bile ducts, especially the left, owing to its straighter course.

Pathology.—Initially infection leads to primary proliferation of the biliary epithelium and thickening of the duct wall ; later this becomes greatly thickened, and finally cirrhosis of the liver with destruction of the parenchyma results (Faust). The pancreatic duct is sometimes involved.

Symptoms.—Mild cases may be symptomless, but the heavier infections show anorexia, epigastric pain, hepatomegaly, diarrhœa, wasting, jaundice, œdema and ascites.

Diagnosis.—This is made by finding the eggs in the fæces.

Prognosis.—This is dependent on the intensity of the infection ; heavily infected cases occasionally die, but mild and moderate ones invariably survive unless some intercurrent disease develops.

Treatment.—Prevention lies in the cooking of freshwater fish before consumption. Tartar emetic intravenously possibly reduces the number of worms, while gentian, crystal and methyl violet reduce the intensity of infection as measured by the egg-cell count. Gentian violet is given as a keratin-coated pill (2½ grains) thrice daily after meals for 10 days ; for intravenous use 40 c.c. of an 0·5 to 1·0 per cent. solution is injected every other day ; not more than 6 g. is advised (Faust).

When the liver is enlarged and tender, bile drainage may be accelerated by concentrated magnesium sulphate fed through a duodenal tube left *in situ*

for several days. It decreases intra-biliary pressure and absorption of toxic material, but does not cure.

HETEROPHYIDIASIS

Definition.—Infection with flukes of the family *Heterophyidæ*. Three genera occur in man.

(1) *Heterophyes heterophyes* (*Distoma heterophyes*, etc.). A minute intestinal fluke infesting man, the dog, cat, etc., in Egypt, measuring 1·0 to 1·7×0·3 to 0·4 mm. The oval, light-brown, operculated ova measure 28 to 30×15 to 17 μ. Though the life cycle is not completely known, the cercariæ encyst in mullet (*Mugil cephalus*), the ingestion of which causes infection.

(2) *Heterophyes katsuradai* differs morphologically in the great size of its acetabulum, etc.

(3) *Metagonimus yokagawai*.—This pear-shaped fluke measures 1 to 2·5× 0·4 to 0·75 mm., while its eggs closely resemble *H. heterophyes*, measuring 26·5 to 28×15·5 to 17 μ. The life cycle passes through *Melania libertina* and allied molluscs, the cercariæ encysting in the edible fish, *Plectoglossus altivelis*.

(4) A number of other heterophyid flukes, including *Monorchotrema taichi*, *M. taihokui*, *Diorchitrema pseudocirrata* and *Heterophyes brevicæca*, have been recorded by Africa and Garcia from Manila.

Pathology.—The flukes become attached to the intestinal mucosa by their suckers, inducing mild inflammatory reactions and eosinophilia.

Symptoms.—Mild digestive disturbances and diarrhœa with blood in the stools may result in severe infections. Often the condition is symptomless, the diagnosis being made by finding ova in the fæces. In their cases in Manila, Africa and Garcia have described a condition of cardiac heterophyidiasis, resembling cardiac beriberi, associated with sclerosis of the mitral valves and fibrosis of the myocardium; heterophyid ova were demonstrated in the local lesions.

Treatment.—Carbon tetrachloride, betanaphthol, thymol, the oleoresin of aspidium, or eucalyptus, castor oil and chloroform mixture are efficacious in eradicating the infection. To find the parasites, the stools must be strained through muslin.

SCHISTOSOMIASIS (BILHARZIASIS)

Definition.—Invasion of man with blood flukes of the family *Schistosomidæ*. Three species are well known—*Schistosoma hæmatobium*, *S. mansoni* and *S. japonicum*. More rarely man may be affected by *S. bovis* and *S. matthei*. *Life cycle.*—The parasites inhabit the portal veins and their tributaries, depositing ova in the hollow viscera, whence they escape via the urine or fæces; on contact with water miracidia emerge, invade the appropriate molluscan intermediary, in which sporocysts and cercariæ develop (Miyairi and Leiper). The latter invade the skin and find their way to the portal system, where the schistosomulæ mature. The tuberculated male, originally a flattish fluke, has become rounded by inrolling of its edges to

form the gynæcophoric canal, in which the thread-like female lies. Both sexes have an anterior, prehensile sucker and a posterior, suctorial sucker by which the worm maintains its position against the portal blood stream.

S. hæmatobium (*Bilharzia hæmatobia*) occurs in Africa and parts of Western Asia, etc. (♂ 10 to 15 mm.×0·8 to 1·0 mm.; ♀ 20 mm.×0·25 mm.). The ova have a sharp terminal spine and measure 120 to 160×40 to 60 μ. The intermediary hosts vary considerably, being *Bulinus contortus*, etc., in Egypt, *Physopsis africana* in Natal, and *Planorbis metidjensis* in Portugal. *S. mansoni* is found in Africa, South America, etc. (♂ 10 to 12 mm.×1·0 to 1·2 mm., ♀ 12 to 16×0·16 mm.). The ova have a lateral spine and measure 140 to 165×60 to 70 μ. The intermediary host is *Planorbis boissyi* in Egypt, and *Physopsis africana* in Natal, etc. *S. japonicum* is confined to the Far East—Japan, China, Formosa and the Philippines (♂ 12 to 20 mm.×0·5 to 0·55 mm., ♀ 15 to 26 mm.×0·3 mm.). The ova possess a lateral knob and measure 100 to 110×55 to 65 μ. The intermediate hosts are *Katayama nosophora*, *K. formosana* and *Oncomelania hupensis*.

Pathology.—In *S. japonicum* and *S. mansoni* the worms are found in the portal system, especially its mesenteric branches, ova being deposited in large numbers in the colon and liver, and to a lesser degree in the small intestine, mesenteric glands, stomach, pancreas and rarely the spleen. In *S. hæmatobium* they wander still farther afield via the inferior hæmorrhoidal plexus into the pelvic plexuses of veins, especially the vesical, prostatic and uterine; eggs are deposited in the bladder, prostate, seminal vesicles, urethra, the lower third of the ureter, cervix and vagina. These plexuses communicate with the inferior vena cava; in consequence stray ova filter out into the lungs rather than the liver. Apart from toxic effects and suctional trauma produced by the schistosomes themselves, the egg deposits cause considerable local inflammatory reaction, at first giving rise to small pseudo-tubercles initially composed of giant cells, eosinophiles and round cells; later these disappear or are replaced by whorls of fibrous tissue in which degenerated and calcified eggs are found. The characteristic papillomata form as a combined result of irritative downgrowth of epithelium produced by toxic substances liberated from worms and ova, and submucous cellular accumulations pressing the mucosa upwards from below.

Special pathology.—*S. japonicum* and *S. mansoni* produce various colonic lesions, including round, whitish, submucous pseudo-tubercles, bilharzial colitis, and papillomata, which may slough off, leaving round ulcers. All these lesions may be visible with the sigmoidoscope. In addition, marked fibroid thickening and contractures of the bowel wall, mesentery and omentum sometimes occur. Periportal cirrhosis of the liver, which may or may not be associated with bilharzial splenomegaly, is met with. Other lesions include rectal papillomata, prolapse of the rectum, perineal granulomata and ischio-rectal fistulæ. In *S. mansoni* egg deposits in the spinal cord may produce myelitis, and granuloma of the brain simulating cerebral tumour is recorded in *S. japonicum*. In *S. hæmatobium* vesical lesions are dominant, but in addition there may be involvement of the ureters (lower third), chronic fibrosis of the prostate and seminal vesicles, bilharzial infiltration of the cervix, vagina and periurethral tissues with sinus formation, and granulomata of the penis and vulva. In the bladder the earliest lesions are minute petechiæ and round, yellowish, pseudo-tubercles studding its surface; later,

papillomata and ulcers may develop, while chronic fibroid thickening and the so-called "sandy patches" are very characteristic of the chronic stages with calcified eggs. These lesions are demonstrable cystoscopically. Pulmonary fibrosis associated with egg deposits is not uncommon, but involvement of the colon and liver is minimal.

Symptoms.—Three stages can be recognised: (1) invasive; (2) toxic or anaphylactoid; (3) localised disease (*a*) early, (*b*) late.

(1) *Invasive.*—The entry of cercariæ may give rise to transient rash and local irritation lasting 24 to 48 hours (Kabure disease).

(2) *Toxic or anaphylactoid.*—Within 2 to 8 weeks a clinical syndrome may appear, characterised by urticaria and an intense eosinophile leucocytosis; in addition there may be rigors, abdominal pain, enlarged, tender liver and spleen, dyspnœa, bronchitis, anorexia, diarrhœa and fever, lasting a few days to several weeks; the severe cases often simulate typhoid. This stage is most marked in *S. japonicum* (Katayama disease), but it is also described by Lawson in *S. mansoni* and by Fairley in *S. hæmatobium*.

(3) *Localised disease.*—Local features dependent on egg deposition in the bladder or colon are not generally apparent for 3 to 9 months after infection. In *S. hæmatobium* early symptoms include scalding or frequent micturition, penile, perineal, suprapubic or loin discomfort or pain, and terminal hæmaturia, the blood being bright red and increased by exercise. At this stage the prostate may be congested and tender, cystoscopic examination shows the characteristic yellow, round pseudo-tubercles, and the urine contains leucocytes, erythrocytes and terminal-spined ova which may also appear in the fæces (40 per cent.). For years intermittent hæmaturia may be the only clinical manifestation, the subsequent course depending on such complications as carcinoma, cystitis with an alkaline urine containing much muco-pus, and renal involvement. In *S. mansoni* localised features may be absent or a chronic bilharzial dysentery may develop, characterised by colicky abdominal pain, the passage of blood and mucus, and tenesmus. Between attacks there is rectal discomfort, but the stools are solid, and coated with mucus, which may contain the characteristic lateral-spined ova. Later periportal cirrhosis and splenomegaly with ascites, etc., may supervene. In *S. japonicum* similar dysenteric symptoms are present. The chronic stage with cirrhosis and splenomegaly is characterised by weakness, emaciation, pallor, secondary anæmia, dilatation of the abdominal veins, and finally ascites and liver insufficiency.

Complications.—In *S. hæmatobium* there may be chronic nephritis or hydronephrosis due to backward pressure, or septic cystitis with pyonephrosis or ascending pyelonephritis. Carcinoma of the bladder, penis or vulva may also ensue, while bilharzia papillomata and vesical calculi are not uncommon. In *S. japonicum* and *S. mansoni* hepatic cirrhosis, liver insufficiency or carcinoma of the liver may supervene.

Diagnosis.—In the early toxic or anaphylactoid stage the diagnosis may be suggested by the intense eosinophilia and confirmed by the cercarial complement-fixation reaction (Fairley). In the localised stage the diagnosis is generally made by finding ova in the excreta, but the complement-fixation reaction, the intradermal skin test (cercarial antigen), and the cystoscopic or sigmoidoscopic findings often prove of great value. In examining for *S. mansoni* or *S. japonicum* the mucus covering of the stool should be selected,

and in *S. hæmatobium* the last few cubic centimetres of urine passed ; several examinations may be necessary and eggs may be found in scrapings from the bowel wall obtained with a blunt curette during sigmoidoscopy, when ordinary fæcal examinations are negative.

Prognosis.—The prognosis is bad in patients continuously exposed to infection, or in late cases when hepatic or renal insufficiency, septic infection or carcinoma has supervened.

Treatment.—PROPHYLACTIC.—This consists in curing the disease in man, in preventing excretal contamination of water, in destruction of snail vectors and in avoiding contact with infected water.

CURATIVE.—Two trivalent antimony compounds, tartar emetic and stibophen (fouadin), as well as emetine hydrochloride, exert a specific lethal action on the adult schistosome. During treatment rest in bed is advisable, especially if complications exist, but in Egypt and elsewhere often ambulatory treatment is alone practicable.

(1) *Tartar emetic*, first successfully introduced by Christopherson, is given intravenously in 10 c.c. of saline every second day, commencing with $\frac{1}{2}$ grain doses and increasing by $\frac{1}{2}$ grain until a maximum of 2 grains is attained. The solution must be freshly sterilised, and the total course for the adult should equal 30 grains. The drug kills the schistosomes, and viable ova rapidly disappear from the excreta. Cough, vomiting and toxic muscular pains may follow its administration, but the drug is generally well tolerated except in cases complicated by hepatic cirrhosis, renal involvement, sepsis, etc. Great care must be taken not to inject the solution into the tissues, as severe inflammation and necrosis result.

(2) *Stibophen* (*fouadin*) (antimony-pyrocatechin-disulphonate of sodium) should be given in an all-glass syringe in 6·3 per cent. solution ; the total course consists of 40 c.c. administered in nine intramuscular injections extending over a period of 15 days. According to Khalil, the therapeutic results compare favourably with those obtained by tartar emetic

(3) *Emetine hydrochloride* is advised by Tsykalas in doses of $1\frac{1}{2}$ grains for 8 to 10 days. Though lethal to schistosomes, toxic complications are liable to develop and now that stibophen is available for intramuscular injections in children there is little justification for its use. The usual medical and surgical measures should be employed for complications as they arise, and rectal and other polyps which do not resolve with specific therapy may need excision with the electric cautery.

N. HAMILTON FAIRLEY.

B. DISEASES DUE TO CESTODES

TÆNIASIS—TAPE-WORMS

Definition.—Tæniasis is produced by different forms of tape-worms occurring either as adults in the intestine (intestinal tæniasis), or as the developmental stage in the muscles and other host tissues (somatic tæniasis).

Intestinal Tæniasis

(1) *Tænia solium* (Linnæus, 1758).—The pork tape-worm measures 2 to 3 metres in length. The head is globular and possesses 4 suckers, a rostellum and a double row of hooks. The uterus never has more than 12 lateral processes (diagnostic). The ova are spherical, 31 to 40 μ in diameter, having a thick-walled shell and an oncosphere with 3 pairs of hooklets. The cysticerus stage is passed in the pig (*Cysticercus cellulosæ*), and man becomes infected by eating undercooked "measly" pork. Pickling and smoking do not kill cysticerci.

(2) *Tænia saginata* (Goeze, 1782).—The beef tape-worm measures 3 to 4 metres in length. Its head is cubical with 4 suckers, but no armature; the uterus contains 15 or more lateral processes, thus differentiating it from *T. solium*, though its oval eggs, measuring 33·40×20·30 μ, may be indistinguishable. The cysticercus stage is found in the ox (*Cysticercus bovis*) and man becomes infected by eating undercooked beef.

(3) *Dipylidium caninum* (Linnæus, 1758).—A common tape-worm of the dog is occasionally found in man. Human infestation with *Tænia confusa*, *Tænia africana* and *Bertiella satyri* has been described on two or three occasions.

(4) *Hymenolepis nana*.—This dwarf tape-worm, which is common in Southern Europe, the Southern United States and India, inhabits the small intestine of man. It measures 2·5 to 4·0 cm. in length, has 4 hemispherical suckers and a short rostellum with a single row of hooks. The eggs measure 30 to 40 microns in diameter and contain an onchosphere. No intermediary host is required, as the eggs hatch out in the intestine. After penetrating the mucosa the embryos develop into cercocysts, return into the lumen of the bowel, become attached by their heads to the villi and develop into mature worms.

(5) *Diphyllobothrium latum* (Linnæus, 1758) (*Tænia lata*, etc.).—The broad, fish tape-worm, some 2 to 10 metres long, possesses an almond-shaped head, but no armature. The immature eggs are oval, operculated and measure 70×45 μ. After 3 to 5 weeks' development in water the hexacanth embryo escapes and is ingested by some species of cyclops or allied crustacean in the body cavity of which it develops into a procercoid larva. Infected crustaceans must be swallowed by certain fish, *i.e.* before the plerocercoid larva develops. Man becomes infected by eating the undercooked, infected fish. Other species, such as *D. cordatum*, *D. parvum* and *D. houghtoni*, have been described on one or two occasions as has also *Diplogonoporus grandis* and *Braunia jassyensis*.

Symptoms.—Symptoms may be absent, or gastro-intestinal disturbances, such as anorexia, voracious appetite, dyspepsia, abdominal pain, colic and diarrhœa may result. Neurasthenia in adults, and headache, convulsions and strabismus are described in children. Occasionally *D. latum* is associated with severe megalocytic anæmia.

Diagnosis. The diagnosis is made by identifying the appropriate segments or ova in the excreta. Skin hypersensitiveness to tape-worm protein and eosinophilia may be present.

Treatment.—Filix mas and carbon tetrachloride are effective remedies for all the tape-worms, provided preliminary starvation and terminal purgation with salines be instituted. After a liquid diet, consisting of broths,

orange juice, dextrose, etc., for 2 days, during which time the bowels are well opened, extractum filicis liquidum in 30 mimim doses is given in gelatine capsules or emulsion at 8.0, 8.20 and 8.40 a.m. In obstinate cases an extra 30 minims may be given at 9 a.m. and 30 minims of oil of turpentine as well. Sodium or magnesium sulphate (gr. 240) is administered at 10 a.m., and all the motions subsequently passed must be carefully sieved and examined against a black background to identify the head; castor-oil must never be used as it dissolves out filicic acid and leads to poisoning. If the head is not recovered, treatment may be repeated in 10 days' time, or 3 months' interval may be allowed, by which time segments will have generally reappeared if the worm has survived. Carbon tetrachloride is given in capsules, the maximum adult dose being 3 c.c.; this is followed by a saline purge 3 hours later. Some report that it is advantageous to combine oil of chenopodium (1 c.c.) with carbon tetrachloride therapy, as in the treatment of ancylostomiasis.

Somatic Tæniasis

(1) *Sparganum mansoni.*—This is the plerocercoid stage of *Diphyllobothrium mansoni* (Cobbold, 1882) which has a somewhat similar life-history to *D. latum*. The adult worm infests the intestine of the dog and cat, the ciliated embryo is ingested by *Cyclops leuckarti* where it develops into a procercoid larva. When swallowed by the second intermediate host, which may be a snake, bird or mammal, including man, the cyclops is digested, the liberated larva penetrates the stomach and, travelling under the peritoneum, reaches the deep somatic muscles, also the iliac fossa, lumbar region, pleura, urethra and eye where it multiplies asexually by transverse fission, many spargana resulting from a single plerocercoid (Faust). Ingestion of sparganа-infested tissues by the dog and cat results in intestinal tæniasis, but the adult stage does not develop in man.

Symptoms.—Pain, swelling and œdema of the subcutaneous tissues and muscles sometimes occur, and in ocular sparganosis, which is common in the Tonkin delta, inflammation with pain, redness, œdema, lachrymation and ptosis may result. Human infection in China often follows the direct transference of spargana from infected frogs which are applied locally in the treatment of ulcers, etc. (Joyeux and Houdemer).

Diagnosis.—This is made by finding the unbranched sparganum larvæ embedded by their scolices in a slimy matrix in the tissues.

Treatment.—Where possible the parasite is removed surgically.

(2) *Sparganum proliferum* (Ijuma, 1905).—This species affects man in Japan, innumerable spargana producing nodules and honeycombing of the tissues, and elephantiasis if the lymph channels be involved. The adult stage and life cycle are unknown.

(3) *Tænia solium.*—The cysticercus stage of *T. solium, i.e.* cysticercosis, is occasionally found in man who may or may not have harboured the adult parasite. The cyst, which is generally surrounded by a fibrous-tissue capsule, consists of an opalescent bladder containing a single evaginated head with hooklets. Various tissues, including the brain and its ventricles, the liver, lungs, orbit and the somatic muscles and heart, may be involved. It occurs in Europe, Africa and Madagascar, and in soldiers returning from India and Egypt. Macarthur has recently found it to be a common source of epilepsy.

Man probably acquires the disease by auto-infection, or eating uncooked food, such as lettuce, to which dried segments of *T. solium* are adherent.

Symptoms.—Subcutaneous nodules ($\frac{1}{2} \times 2$ cm.), muscular weakness, cramp and pains may be encountered, also Jacksonian epilepsy, petil mal, various psychoses and occasionally focal lesions of different types, if the brain be involved (*Cysticercus cellulosæ*). The diagnosis is established by biopsy of a subcutaneous cyst, or X-ray examination revealing calcified nodules in the muscles. Ophthalmoscopic examination may show retinal lesions, while eosinophilia and skin hypersensitiveness and positive complement-fixation reactions with tænia antigens may be found. Accessible cysts can be excised, but the prognosis is bad if the brain be involved. The most dangerous period is the sixth to the eighth year, when cerebral disturbances most frequently occur. Mental deterioration and death generally result, but occasionally even those developing cysts recover. Fits should be controlled by luminal and bromide.

(4) *Tænia multiceps* (Leske, 1780).—*Cœnurus cerebralis*, the cystic stage of the canine tape-worm, *T. multiceps*, commonly affects the brain of goats and sheep; it has been recorded in man, producing epilepsy and aphasia.

(5) *Echinococcus granulosus* (Batch, 1786).—This small tape-worm (2·5 to 6 mm. in length) inhabits the intestines of dogs, jackals and wolves; it consists of a head with 4 suckers, a rostellum and hooklets and 3 or 4 segments, of which only the terminal one is gravid. In the intermediate hosts, which include sheep, cattle, pigs and man, hydated disease is produced. Man becomes infested from swallowing water and uncooked vegetables, etc., contaminated with infected canine fæces, or by handling and fondling infected dogs. Hydatid disease is frequently contracted in childhood and is most common in sheep-breeding countries like Australia, New Zealand, the Argentine and South Africa; it also occurs in Iceland but is less frequently encountered in Europe.

After the egg is swallowed, the six-hooked embryo escapes from its shell, traverses the intestinal wall, invades the blood vessels, and metastasises generally in the liver, but less frequently in the lungs, brain, bones, and muscles, etc., where it loses its hooks and forms a cyst, the wall of which consists of two layers, a laminated outer layer, the ectocyst, and a granular inner layer, the endocyst. As the cyst grows, it exerts mechanical pressure and toxic effects on adjacent host tissue, resulting in inflammatory reaction and the formation of a fibrous tissue capsule known as the adventitia. Endogenous budding from the granular layer of the cyst results in the formation of brood capsules, scolices, and daughter and granddaughter cysts. Exogenous budding sometimes occurs, especially in bone, while atypical development in viscera like the liver may result in alveolar or multilocular types of hydatid. It is improbable that a second parasite, *E. multilocularis*, exists.

Symptoms.—The clinical picture is very varied. Cysts may be symptomless for many years until pressure effects are produced, or they may rupture or suppurate with the production of acute illness. Rupture into a vein may lead to sudden death from an embolus of daughter cysts, or to an anaphylactic syndrome characterised by injected conjunctivæ, lachrymation, vasomotor collapse, urticaria, œdema, respiratory distress and eosinophilia. Rupture into the peritoneal cavity may produce an acute abdominal crisis followed by peritoneal echinococcosis, secondary cysts developing from scattered scolices, or if the cyst rupture into a bronchus natural cure may ensue. Suppuration,

especially of liver cysts, is not uncommon, while in some 30 per cent. of cases their degeneration and death with subsequent calcification lead to natural cure. The inferior aspect of the right half of the liver is the commonest site affected, while the right lung is three times as often involved as the left. Brain cysts closely simulate cerebral tumour, while echinococcosis of bone, owing to its rapid exogenous growth, often leads to a fatal issue, especially when the pelvis and vertebral column are involved ; a pressure myelitis may result.

Diagnosis.—A history of contact with dogs in childhood is important ; hydatid thrill, if present, is pathognomonic. Collapsed cysts, membrane, scolices and hooklets may be coughed up or passed per rectum, while the aspiration of a clear watery fluid containing considerable amounts of sodium chloride and hydatid elements clinches the diagnosis. Aspiration, however, should never be carried out in lung cysts except on the operating-table owing to the danger of drowning from rupture into the bronchial tract. X-ray examination is of considerable importance in localising liver and lung cysts, while the complement-fixation and precipitin reactions and the intradermal test have greatly increased the percentage of cases correctly diagnosed before operation. Eosinophilia may occur, especially if a cyst has recently ruptured.

Treatment.—No medical treatment is available except for the anaphylactic syndrome, when adrenaline (10 min. of 1 in 1000 solution) should be administered. As a rule, calcified cysts should not be operated on. After the injection of formalin to kill scolices in hepatic cysts the contents should be evacuated and the adventitia sewn up in smaller sized cysts ; suppurating and large cysts must be drained. Special care must be taken to prevent soiling of the peritoneum with the cyst contents in hepatic hydatid, as secondary peritoneal echinococcosis is liable to develop.

G. CARMICHAEL LOW.
N. HAMILTON FAIRLEY.

C. DISEASES DUE TO NEMATODES (ROUND-WORMS)

STRONGYLOIDIASIS

Strongyloides stercoralis (Bavay, 1876).—A common tropical parasite of man, the female worms living in the jejunum and duodenum, and in massive infections invading the bile and pancreatic ducts, the stomach and colon.

Ætiology.—The eggs hatch out rhabditiform larvæ which appear in the fæces : rarely, where intense diarrhœa is present, the eggs (50–80 × 30–34 μ), which resemble ancylostome ova, may be found. The rhabditiform larvæ give rise either directly, or indirectly through a sexual circle, to filariform larvæ which invade the skin or mucosa and follow a similar route to ancylostomes proceeding via the lung to the intestine.

Pathology.—Intestinal catarrh or an enteritis, with extensive erosions of the mucosa, giving rise to a " beefsteak " appearance, may occur in heavy infections.

Symptoms.—Initial dermatitis and lung symptoms may be seen during the first few days. Mild infections show no symptoms ; severer infections

may present epigastric discomfort after meals, flatulence and diarrhœa which occasionally is very intractable. Occult blood may occur, urticaria and œdema sometimes develop at the site of entry of infective larvæ, and dermal sensitivity can be demonstrated to strongyloid extracts (Fülleborn).

Diagnosis.—This is made by finding the rhabditiform larvæ in the stools, which should be mixed with water and strained through muslin. Hook-worm embryos have a longer pre-œsophageal mouth cavity and occur within the egg.

Treatment.—Gentian violet, recently introduced by De Langar, appears to be a specific when given as a keratin-coated pill (1 grain) thrice daily before meals. It is best administered in two courses, each lasting 8 days, separated by a week's interval, during which no gentian violet pills are taken.

Allied helminths, including *Rhabditis pellio* (Schneider, 1886) and *Turbatrix aceti* (Müller, 1783), the common vinegar worm, have been reported in the vaginal exudate and urine of women.

FILARIASIS

An invasion of man by members of the family *Filariidæ*. Several species are known to infest man, *Filaria bancrofti* or *Wuchereria bancrofti*, *Filaria loa* and *Loa loa*, *Filaria perstans* or *Acanthocheilonema perstans* transmitted by *Culicoides austeni*, and *Filaria ozzardi* or *Mansonella ozzardi*, the insect vector being *Culicoides furens*. Only the first two are of clinical importance. Two larval *Filariidæ* are known in which the adults have not been found—*Microfilaria malaya* (Brug, 1927) occurring in the peripheral blood at night, and *Agamofilaria streptocerca* (Macfie and Corson, 1922) found commonly in the skin of natives on the Gold Coast.

(1) *Filaria bancrofti* (Cobbold, 1877).—This parasite has a widespread tropical distribution, being especially common in India, the West Indies, Porto Rico, Southern China and the Pacific Islands. The adults are like fine catgut (♂30 40 mm. long; ♀ 76–100 mm.×0·2 mm.); they inhabit the lymphatics and periglandular lymphatic tissue, and produce embryos which subsequently invade the blood stream, living in the lungs and thoracic blood vessels by day and appearing in the peripheral blood only at night—noctural periodicity. The embryos are enclosed in a loose sheath and measure 230–320×7·5–10 μ. As Manson first showed, the intermediate host is a mosquito (chiefly *Culex fatigans*), which sucks the embryos out of the blood at night; metamorphosis subsequently takes place in the thoracic muscles. The mature embryos are inoculated into man via the proboscis (Low). Development in the insect vector takes from 10 to 40 days, depending on the temperature, etc. In the Pacific where *F. bancrofti* is transmitted by *Aëdes variegatus*, which bites in the daytime, the filaria is non-periodic in type. It is possible, however, that this filaria is of a different race or sub-species.

Pathology.—The parent worms may produce little damage: at other times they injure the lymphatics, causing filarial lymphangitis, abscess, varicose groin glands, chylocele, lymph scrotum, filarial orchitis, hydrocoele, chyluria, chylous ascites and elephantiasis which often involves the lower extremities, scrotum or vulva. These changes are partly mechanical and partly attributable to helminthic toxins and secondary streptococcal infec-

tion, which induce lymphangitis and inflammatory changes in the tissues, resulting in fibrosis, obstruction and lymph stasis.

Symptoms.—The disease is symptomless unless obstruction to the lymph-flow and lymphangitis ensue; the latter is associated with rigors, high fever, tender enlargement of lymphatic glands and inflammatory swelling of the affected parts. O'Connor has recently described palpable focal spots, consisting of dead worms from which the lymphangitis may radiate upward or downward in the limb. Filarial abscess associated with death of parent filariæ may form in the limbs and scrotum, and is generally complicated by secondary bacterial infection. Filarial orchitis (endemic funiculitis) is really a lymphangitis involving the spermatic cord. Recurrent attacks may lead to hydrocoele. In lymphuria and chyluria the patient often passes white, milky urine which may be mixed with blood. Other clinical manifestations depend on the site and nature of the lesions.

Diagnosis.—The presence of an unexplained eosinophilia may suggest searching the blood for embryos, while the intradermal test, using *Dirofilaria immitis* extract as antigen, is of value in distinguishing the non-filarial from filarial types of elephantiasis where embryos have generally disappeared.

Treatment.—Prophylaxis depends on mosquito destruction and the use of mosquito nets, etc. No specific drug treatment is known, but the application of an ethyl chloride spray to focal points has been recently advocated to abort lymphangitis. Where secondary streptococcal infection has supervened, sulphonamide therapy is indicated. Surgical intervention may be necessary for various elephantoid conditions. In elephantiasis of the legs elastic bandaging, massage and rest, with elevation of the limbs, are desirable. Elastic stockings should be washable, porous, and made to fit, extending from the dorsum of the foot to above the knee.

(2) *Loa loa* (Cobbold, 1864).—Human infestations with this parasite occur in West Africa. The adults inhabit the subcutaneous and retroperitoneal tissues, while the sheathed embryos have a diurnal periodicity (9 a.m. to 9 p.m.); several years may elapse before embryos appear in the peripheral blood. Transmission is by certain species of mango-fly (*Chrysops dimidiata* and *C. silacea*) which feed in the daytime. Clinically the worms give rise to urticarial eruptions and puffy, painless, white swellings the size of a hen's egg, lasting 2 to 3 days, known as Calabar swellings. These are due to an œdema of the subcutaneous tissue and probably represent an anaphylactoid reaction to helminthic products or toxins. Leucocytosis associated with a marked eosinophilia (20 to 60 per cent.) is characteristic, and dermal hypersensitiveness to diro-filarial extract is shown in almost every case. Positive complement-fixation reactions are also given with diro-filarial alcoholic extracts. Neuritic pains may also be complained of. Not infrequently the worms appear about the eye, and in their migration across the conjunctivæ give rise to transient conjunctivitis and lachrymation. Where visible, the worm should be surgically removed under local anæsthesia.

ONCHOCERCIASIS

Onchocerca volvulus (Leuckart, 1893).—This nematode, found on the west coast of Africa, inhabits the subcutaneous or connective tissues of man,

often giving rise to nodular, subcutaneous, cystic tumours, 1 to 10 cm. in diameter, over which the skin is generally movable, and in which lie entangled masses of worms and embryos encased in dense fibrous tissue. The swellings are particularly common around the elbows, knees, ribs, iliac crests and great trochanter. Unsheathed microfilariæ may occasionally be demonstrated in the skin, especially of the loin and thigh, as well as in the circulatory blood and subcutaneous lymph channels, even though no evidence of disease exists. Dermal lesions, including achromia, xeroderma and pseudo-ichthyosis, are attributed to embryos located in the skin (Laigret). Pruritus may be intense, especially at night. Onchocerca tumours of the head are not infrequently associated with ocular complications. Blindness may result from retino-choroiditis or punctate iritis when embryos are found in the anterior chamber. Blacklock has shown that transmission is by the buffalo gnat, *Simulium damnosum*. Localised tumours may be removed under local anæsthesia.

The parasite called *Onchocerca cæcutiens* (Brumpt, 1919) is found in Guatemala and Mexico. Its status as a distinct species has for some time been doubtful, and the recent work of Strong indicates it is the South American form of *O. volvulus*. It produces flat nodes (Guatemala nodules) up to 2 cm. in diameter, especially affecting the scalp and face, and an eruption known as "coastal erysipelas," associated with pain, tumefaction and fever may result from secondary streptococcal infection of the skin due to scratching, the irritability being caused by microfilariæ in the corium. More important are the ocular lesions caused by microfilariæ, piercing the capsule of the nodules and invading the tissues of the eye, producing conjunctivitis, punctate iritis, keratitis and choroiditis. Blindness commonly follows (Strong). An eosinophile leucocytosis is the rule. Diagnosis is made by demonstrating the microfilariæ in the milky fluid aspirated from the nodules, or in adjacent pieces of skin shaved off and teased up in saline at 37° C. for microscopical examination. Transmission is by three different species of *Simulium*, the coffee flies living at a height of 2500–5000 feet. The nodules should be excised whenever possible, especially those in the vicinity of the eyes. Some improvement in the ocular condition may follow this procedure.

DRACONTIASIS

Dracunculus medinensis (Linnæus, 1758). — Guinea-worm disease is common in India, Persia and Africa. The adult female, measuring 40–120 cm. ×0·5–1·7 mm., inhabits the subcutaneous and interstitial tissues, and takes some 12 months to reach the skin where it secretes some toxin producing a blister which later ulcerates, and permits, on contact with water, the reflex discharge of embryos from the prolapsed uterus which perforates the base of the ulcer. The worm itself is often surrounded by a fibrous-tissue canal. Fedtschenko, in 1879, produced evidence that a cyclops was the intermediate host. Man becomes infected by swallowing these crustaceans in drinking water.

Pathology.—Three factors are responsible for pathological lesions, namely, the worm, the embryos and secondary bacterial invaders. The toxic substance responsible for blister formation may, if absorbed, lead to anaphylactoid symptoms. Premature ejaculation of embryos may produce

subacute sterile abscess. Bacterial invaders, especially *Staphylococcus aureus*, *Bacillus coli* and streptococci are responsible for acute abscess, cellulitis, bubo, synovitis, arthritis and septicæmia; these complications almost invariably result from the retraction into the tissues of a taut, elastic worm, broken during efforts to extract it.

Symptoms.—Prodromal symptoms consist of an itchy, urticarial eruption (40 per cent.) which may be associated with vasomotor collapse, vomiting, diarrhœa, dyspnœa and high eosinophilia followed a few hours later by blister formation and ulceration (Fairley). The lower extremities are commonly involved (86·5 per cent.), and in decreasing frequency the arms, trunk, buttock and scrotum. Septic complications are frequent, and contracture of tendons and fibrous ankylosis of joints sometimes result. Neuritis and muscular rheumatism may be produced by calcified worms, which on X-ray examination show a pathognomonic, convoluted, moniliform shadow.

Treatment.—This depends on the stage at which the patient is seen. Anaphylactoid symptoms are best treated by injections of adrenaline (min. x. of a $\frac{1}{1000}$ solution). A blister, if present, should be aspirated. Once an ulcer has formed it must be treated with antiseptic dressings and the worm subsequently extracted either by intermittent traction and massage, or by multiple incisions under local anæsthesia. The outline of the worm becomes more obvious if the tissues are sprayed with ethyl chloride. When the worm is closely convoluted the whole area may be excised *en masse*. The old method of gradual extraction by winding round a match and daily douching with water until the uterus is emptied still has its advocates. Localised abscess must be treated by passing a probe through the sinus and slitting up the canal in which the worm lies. Other complications are treated along general surgical lines.

TRICHINIASIS

Definition.—A disease produced by the embryos of *Trichinella spiralis* (Owen, 1835) during their migration from the human intestine to the muscles.

Ætiology.—Infection is acquired by eating raw or underdone pork in which the larvæ have encysted. After the cyst walls have been dissolved by the gastric juice the embryos mature and breed in the small intestine. The gravid female bores into the mucosa, depositing hundreds of viviparous larvæ (100×6 μ) which reach the muscles from about the ninth to the fortieth day via the liver, lung and left heart. The adults are small (♂ 1·4–1·6 mm.$\times$0·04 mm.; ♀ 3–4 mm.$\times$0·6 mm.) and live only a few weeks, whereas encysted larvæ may survive for 25 years, though they often calcify within 6 months. Rats act as reservoir hosts.

Symptoms.—For the first week during the invasion period gastro-intestinal symptoms develop with nausea, vomiting, colic and diarrhœa with perhaps blood and mucus; then when migration of larvæ commences myositis of the tongue, laryngeal and intercostal muscles and the diaphragm occurs, giving rise to difficulty of swallowing, speech and respiration. The muscles of the jaws, arms, legs and abdomen may also be involved with stiffness and pain; the affected areas are exquisitely tender and hard to the touch. Œdema, especially of the face, urticaria, leucocytosis with high

eosinophilia, prolonged remittent fever (102°-104° F.) and sweating are characteristic. Pulmonary features are common, and occasionally hæmoptysis occurs. Cachexia develops and, finally, during the period of larval encystment, the patient may succumb from toxæmia with respiratory disturbance and coma.

Diagnosis.- Early, the disease may be mistaken for ptomaine poisoning, enteritis or dysentery, and later for rheumatic fever or typhoid. The intense eosinophilia should arouse suspicion, while later biopsy of a piece of the affected muscle such as the deltoid at its tendinous insertion will often reveal precystic or encysted larvæ. Embryos may be found in the blood, especially from the twelfth to the twentieth day, by laking it with ten volumes of 3 per cent. acetic acid and centrifuging the deposit. Intradermal and precipitin tests are often positive to an antigen manufactured from the embryos (Bachman). At a late stage, calcified cysts may sometimes be visualised by X-ray.

Prognosis.—This largely depends on the intensity of the infection, the mortality rate varying in different outbreaks from 1 to 30 per cent. Convalescence is often slow and muscular atrophy may follow.

Treatment. —PROPHYLACTIC.- This depends on careful meat inspection, and adequate boiling of pork; curing by smoking and salting is ineffective. Special care should be taken at autopsy to prevent infection.

CURATIVE.--No specific treatment is known, but every effort should be made to expel the adult worms. Purgatives and glycerin, santonin, thymol and turpentine are employed for this purpose.

ŒSOPHAGOSTOMIASIS

(1) *Œsophagostomum apiostomum* (Willach, 1891).—This nematode frequently affects certain anthropoid apes and monkeys in West Africa, and not uncommonly man in Northern Nigeria. The rhabditiform larvæ exsheathe in the cæcum, invade the bowel wall and give rise to inflammatory nodules in which they develop; later they erupt into the intestine and mature. Dysentery-like symptoms, with hæmorrhage and occasionally peritonitis and septicæmia, may result. The ova are indistinguishable from ancylostome eggs, but fortunately thymol, oil of chenopodium and carbon tetrachloride are specific for the adults (Faust).

(2) *Œsophagostomum stephanostomum* (Raillet and Henry, 1909).—The adult worms present minor differences, and in the only human case recorded, by Thomas in Manaos, Brazil, nodules were found in the ileum as well as in the colon.

ANCYLOSTOMIASIS

Synonyms.—Uncinariasis; Hookworm Disease.

Definition.—Ancylostomiasis is caused by members of the family *Ancylostomidæ*. Five species may affect man—*Ancylostoma duodenale* (Dubini, 1843), *Necator americanus* (Stiles, 1902), *Ancylostoma malayanum* (Alessandrini, 1905), *Ancylostoma braziliense* (Gomez de Faria, 1910), and the *Ancylostoma caninum* (Ercolani, 1859). The first two species commonly

affect man, the third and fourth rarely, while the larvæ of the fifth may cause creeping eruption.

Ætiology.—*A. duodenale.*—Adults ♂ 8–10 mm.×0·4–0·5 mm.; ♀ 12–18 mm.×1 mm. Ova are elliptical, thin-shelled containing vitellus, segmented into 2 to 8 spherules, and measure 55–65×32–45 μ. *N. americanus.*—Adults ♂ 7–9 mm.×0·3 mm.; ♀ 9–12 mm.×0·4 mm. The ova measure 64–75×36–40 μ. The buccal armature of the two species differs. The capsule is smaller in *N. americanus*, and has an irregular border instead of the four ventral hook-like teeth of *A. duodenale*; there is also a pair of semilunar plates. All subsequent description applies to both these parasites.

When fæces containing ova are deposited on moist earth the rhabeditiform larvæ hatch out in 24 to 48 hours: later they moult twice, developing into filariform larvæ which may remain viable for 3 to 4 months. On, contact with human skin the latter bore their way into the blood vessels, pass to the right heart and lungs whence they progress via the trachea, œsophagus and stomach to their natural habitat in the duodenum and small intestine; here they mature and breed, egg-laying commencing in about 5 weeks. The worms attach themselves firmly to the mucosa, feeding on blood and may cause local bleeding (especially *A. duodenale*), though the stools generally give a negative test for occult blood. At autopsy œdema of the legs and sacrum are common, and effusions and petechiæ may involve the serous sacs. The heart is dilated and shows marked fatty degeneration, as do also the liver and kidneys. The duodenum and jejunum may present petechial hæmorrhages, especially at points where the worms are attached.

Symptoms.—At onset the larvæ may produce ancylostome dermatitis or ground itch, which clears up within 2 weeks unless secondary infection has occurred. In heavy infection symptoms may appear within 1 to 2 months. These are largely related to the anæmia which is microcytic and hypochromic in type; there is a low colour index, and an increased blood volume. The counts in a severe case would show R.B.C.'s—1,000,000–2,500,000 per c.mm.; hæmoglobin = 10–25 per cent.; colour index = 0·5. Leucocytes are normal or slightly increased in number, and eosinophilia is characteristic. Mild cases may be symptomless, and it is uncommon for the well-fed European to develop anæmia even when severely infected. Anæmia rarely occurs except in patients living on a borderline diet, poor in animal protein and iron-containing foods. Those moderately infected may complain of mental and physical lethargy, hyperacidity, epigastric tenderness, palpitations, and shortness of breath. The really severe case may show a tallow-yellow discoloration of the alæ nasi and forehead, a dry, earthy-coloured skin, pallor of the mucous membranes, mental sluggishness, dilated stomach and epigastric tenderness; earth-eating sometimes occurs and constipation is frequent. Dyspnœa, cough, palpitations, pulsating cervical veins and hæmic murmurs are common; retinal hæmorrhage, œdema of the feet and serous effusions may occur. Hook-worm disease causes great economic loss to the community by lowering the individual's physical and mental capacity for work and predisposing to secondary infections like pneumonia and dysentery. In Europe outbreaks have sometimes occurred in miners.

Diagnosis.—A microcytic, hypochromic anæmia, especially if associated with eosinophilia, should arouse suspicion in a tropical patient, and the

stools should be immediately examined for ova, preferably by the Clayton-Lane flotation method.

Prognosis.—The mortality rate varies from 1 to 3 per cent., the chief danger being anæmia, which predisposes to intercurrent disease unless specific treatment be instituted. Hook-worm infection is especially serious in children owing to its effects on their mental and physical development.

Treatment.—PROPHYLACTIC.—This includes the treatment of carriers, the substitution of latrines for promiscuous defæcation, the proper disposal of night soil, the treatment of contaminated ground and the wearing of good shoes and boots. Sanitation in mines must be satisfactory.

CURATIVE.—Many drugs have been used. The best are betanaphthol, thymol, oleum chenopodii, carbon tetrachloride, carbon ethyltetrachloride, tetrachlorethylene, and hexylresorcinol. After relative starvation or light dietary for 1 to 2 days combined with saline purgation, 30–60 grains of well-triturated thymol, mixed with an adequate quantity of milk sugar to prevent agglomeration of the crystals, are given in cachets, or 0·5 c.c. of oil of chenopodium at 6, 8 and 10 a.m., followed by magnesium sulphate (gr. 480) at noon. Some follow up a thymol treatment by oil of chenopodium one week later; the latter drug is especially valuable for associated ascaris and strongyloides infections, or if eggs have reappeared. Carbon tetrachloride, or the purified carbon ethyltetrachloride, is given to adults in doses of 3 c.c. either in liquid form or in hard gelatin capsules, but preliminary starvation is not advisable. The combination of carbon tetrachloride (3·0 c.c.) with oil of chenopodium (1·0 c.c.) is very effective; a light supper but no breakfast is allowed, and a saline purge is taken 2 to 3 hours afterwards. Tetrachlorethylene is given in doses of 3 c.c., and hexylresorcinol up to 1 g. may be administered in gelatin capsules; both are followed by sodium or magnesium sulphate purgation. Occasionally any of these drugs may cause poisoning. Thymol solvents including alcohol, fats, *i.e.* butter and milk, castor-oil, ether, glycerin and chloroform must be avoided as they lead to excessive absorption of thymol. With carbon tetrachloride, which occasionally induces acute liver atrophy, dextrose and calcium salts can, with benefit, be administered beforehand; it should not be used where there is fever or hepatic, renal, pulmonary or heart disease, or calcium deficiency. After purgation, the object of which is to get rid of both drug and parasites, the stools are examined and the number of worms counted; 7 to 10 days later the stools are re-examined; if ova have reappeared, then another course, preferably with a different drug, is advisable.

Anæmic patients should receive a diet rich in animal protein and iron-containing foods; and, in addition, iron in full doses should be administered.

ASCARIASIS

Definition.—An intestinal infection of man with the round worm *Ascaris lumbricoides* (Linnæus, 1758).

Ætiology.—Adults ♂ 17–25 cm. × 3 mm.; ♀ 20–40 cm. × 5 mm. The eggs are yellow, elliptical, possess a thick outer shell and measure 50–70 × 40–50 μ. Ova passed in human fæces develop in night soil, and the fertilised eggs, swallowed by man in contaminated water or food, pass into the intestines where the larvæ penetrate the bowel wall and migrate to

the lungs, sometimes producing ascaris pneumonia; thence, via the trachea and œsophagus, they reach the intestine (Stewart). Ova appear in the fæces in 2 to 2½ months.

Symptoms.—During larval migration urticaria, ascaris pneumonia, and, more rarely, ascaris nephritis may occur. Pulmonary complications appear early in the first week and are generally transient in nature. Adult worms may produce symptoms by toxic, reflex or mechanical means. Sensitised individuals occasionally develop rashes such as urticaria and œdema of the face, and in children, gnashing of the teeth, enuresis and convulsions are described. Reflex dyspnœa, abdominal pain and diarrhœa, with or without blood, may occur (ascaris dysentery), while masses of coiled-up worms sometimes produce acute intestinal obstruction. Perforation of the intestine leads to peritonitis or localised abscess from which worms may be discharged. Wandering worms may produce appendicitis or obstruct the pancreatic or bile ducts causing jaundice, or reach the liver producing liver abscess or cholecystitis. They have been known to enter the larynx and cause œdema of the glottis or even to appear in the antrum of Highmore.

Treatment.—Oil of chenopodium (1½ c.c.) carbon tetrachloride and tetrachlorethylene (3 c.c.) are specific remedies; in combination given as in ancylostomiasis they are particularly efficacious (see Ancylostomiasis). Santonin (3–5 grains) is the stock remedy; it may be given on consecutive or alternate days on three occasions combined with preliminary starvation and followed by castor-oil; in children, where the dosage is proportionately lowered, it may be combined with scammony or castor-oil. Hexylresorcinol in 1 g. doses is also recommended and should be followed by a saline purgative. Worms sometimes take 48 hours to be ejected, and the only index to cure is the permanent disappearance of ova.

TRICHURIASIS

Definition.—An infection of the human intestine with the whip worm *Trichuris trichiura* (Linnæus, 1771), formerly known as *Trichocephalus dispar*.

Ætiology.—Adults, 40–45 mm.; 45–50 mm. Ova are brown, barrel-shaped with terminal knobs and measure 50–54 × 23 microns. Man is infected by swallowing the fertilised eggs in food and water; on reaching the cæcum the larvæ are liberated and attach themselves to the mucosa. Occasionally they invade the appendix, colon and terminal ileum.

Symptoms.—Clinical features are generally entirely absent, but reflex symptoms are described in children and occasionally urticaria and eosinophilia are induced. Rarely verminous appendicitis and peritonitis may result, and possibly cæcal lesions may open up the way for other infections.

Treatment.—Thymol and oil of chenopodium may be effective, but worms are often difficult to eradicate.

ENTEROBIASIS

Definition.—Infection by the thread or pin worm *Enterobius vermicularis* (Linnæus, 1758), formerly known as *Oxyuris vermicularis*. Adults

♂ 3–5 mm.; ♀ 10 mm.×0·6 mm. The ova measure 50×20 μ, and are thin-shelled, colourless, plano-convex and contain coiled embryos; they are rarely found in the fæces, being mainly liberated in the perianal region from migrating gravid female worms at night, after the patient has gone to bed. The maximum length of the life cycle is 30 days, long-standing enterobiasis resulting from autoinfection via the infected fingers of the patient.

Symptoms.—The worms inhabit the colon, and when the patient is warm in bed at night may produce great discomfort and itching by migrating out through the anus. Eczema and pruritus ani may result causing sleeplessness and neurasthenia. Sexual disorders, vesical irritability, frequent micturition, prolapsus ani and mucoid secretion may be observed, also in young girls vaginal discharge. Catarrhal appendicitis sometimes occurs, and worms may wander into the stomach.

Diagnosis.—Eggs are best demonstrated by swabs made from the perianal skin. Inspection of the anal region at night immediately when itching commences may reveal the gravid female worms outside the anal canal before they have had time to retreat to the rectum.

Treatment.—The secret of successful treatment is the prevention of auto-infection. This is best done by the most scrupulous care of the hands and nails which may become contaminated (1) by scratching in the anal region, especially during sleep, (2) when completing the anal toilet with sanitary paper, or (3) from infected clothes. The nails should be kept short, and the hands well washed and scrubbed with carbolic soap immediately on waking, after defæcation, and every time there has been possible contact with infected material or clothing. Bathing drawers or pyjamas should be worn at night and sterilised each day, and infected children should occupy separate beds. Enemas of 4–8 fl. ozs. of hypertonic saline solution should be injected immediately the anal irritation commences, for at this time the worms are accessible and can be washed out from the rectum (Macarthur). The process should be repeated each night whenever anal irritability recurs. If re-infection be prevented this measure alone will generally result in cure.

Gentian violet appears to exert a specific lethal effect on the adult worms. Wright has recently advocated special keratin-coated tablets of this drug, the adult dose being 1 grain thrice daily before meals for 8 days; this course is repeated after a clear interval of 7 days. Toxic features include anorexia, nausea, abdominal cramp and vomiting. Over 90 per cent. cure is claimed.

G. Carmichael Low.
N. Hamilton Fairley.

D. DISEASES DUE TO INJURIOUS ARTHROPODS

TICK BITES

Apart from relapsing fever, tularæmia and certain typhus-like fevers the bites of several species of ticks, including *Dermacentor andersoni, D. venustus, Hæmophysalis punctata, Ixodes ricinus* and *I. holocyclus*, may give rise to paralysis in man. Cases have been recorded from Australia, South

Africa and the United States. The incubation period varies from several hours to 6 days; the bites, which are generally situated on the nape of the neck, are painful and œdematous, and the disease, which is afebrile, may be fatal, especially in children. The paralysis is of lower motor neuron type resembling that seen in infantile paralysis, and develops first in the legs and later in the arms and neck. In removing ticks the parasite should not be forcibly extracted until paraffin or carbolised oil has been applied, as this causes withdrawal of the head and so prevents it being broken.

MITES

Apart from scabies, camel itch and copra itch, all of which are caused by different species of mites, several typhus-like fevers, including tsutsugamushi fever, are transmitted by these minute acarines. The harvest mites of temperate climates cause considerable itching and skin erythema, which comes on 12 hours after exposure and increases for 36 hours, sometimes persisting for several days. It may be prevented by sprinkling talc powder and sulphur or powdered naphthalene on the stockings, and is best treated by washing the legs with benzine, green soap or salt solution, while the itchiness can be combated, as in flea-bite, by the use of 1 in 10 carbolic lotion or an ointment composed of acid. carbol. (gr. 10), menthol (gr. 5), zinc oxide (gr. 60 and adip. præp. (1 oz.) (Roxburgh) may be used. Larval mites of the family *Trombididæ* are known to cause skin eruptions in various parts of the tropics. One, in the West Indies, produces red mite dermatitis (bête rouge), the little crimson spot in the middle of the itchy papule being diagnostic: another, in Mexico, has a predilection for the skin of the eyelids, prepuce and axilla. Owing to the fact that many adult mites have never been identified, species names are not generally available for the larvæ.

TONGUE WORMS

The adults, which are degenerated, segmented arachnids superficially resembling tape-worms, live in the lungs or nostrils of certain carnivora or ophidia, and deposit their eggs on vegetation; when these are eaten the larvæ encyst in the viscera of the intermediate host. Only two species have been reported in man, *Linguatula serrata*, which occurs in parts of Europe and Brazil, the larvæ encysting harmlessly in the human liver, and *Porocephalus armillatus*, which encysts in the mesentery, liver and lungs. The infection is not uncommon in the Belgian Congo. Pulmonary symptoms have been reported, and sometimes the larval forms wander free in the peritoneal cavity. If the cysts have become calcified they may be detected by X-ray examination (Low and Cordiner); otherwise the disease is only recognised at autopsy. No treatment is known.

INSECT BITES

Apart from specific disease transmission, bites from mosquitoes, biting flies, midges, lice, fleas, bugs, bees, ants, wasps and hornets may cause con-

siderable inconvenience to man and occasionally result in local sepsis or septicæmia, both of which may end fatally. Mosquito bites occasionally give rise to streptococcal septicæmia, and those of horse flies to anthrax.

Locally, insect venom may have hæmolytic, neurotoxic or irritant effects producing limited inflammation, or the dermal whealing which results may have an anaphylactoid origin dependent on previous sensitisation, as Boycott has proved for midge bites. The stings of bees, wasps and hornets are invariably painful, and in certain situations like the tongue and fauces may lead to respiratory obstruction, or in the larynx to death from œdema of the glottis. Anaphylaxis may follow bee or wasp stings in a sensitised individual. Such patients may suffer from profound vasomotor collapse, become comatose and die in 20 minutes. In a case of wasp sting seen by us the patient, who gave a history of having been stung on the scalp 6 years previously, was again stung on the third right finger; a wheal about 2 cm. in diameter rapidly appeared with surrounding erythema, and within 5 minutes the patient developed headache, lachrymation and injection of the conjunctivæ. Giddiness, nausea, severe vomiting, rapid low tension pulse with vasomotor collapse, generalised urticaria, especially involving the arms and neck, and respiratory distress followed; 3 hours later the general condition was greatly improved, but next day there was a large, puffy, painless swelling involving the subcutaneous tissues of the whole hand. The early and late local effects closely resembled those observed in the immediate and delayed intradermal reactions for hypersensitiveness to helminthic protein.

Treatment.—Mosquito, midge and fly bites may to some extent be prevented by the use of essential oils such as citronella applied to the clothing. They should be treated by the immediate application of iodine, the subsequent itching being relieved by a 1 in 20 watery solution of carbolic or a 1 per cent. alcoholic solution of menthol. In bee and wasp stings, the sting should be carefully lifted or scraped out, as pressure expels the contents of the poison sac. Ammonia, alkaline soap or methylene-blue may be applied locally for the acid bee stings, and vinegar for the alkaline wasp stings. Adrenaline (min. 10 of 1 in 1000 solution) should be immediately injected subcutaneously whenever anaphylactic symptoms develop. Sepsis is treated along the usual lines.

MYIASIS

Definition.—An invasion of the tissues by larvæ of dipterous insects.

Ætiology.—Many flies deposit their eggs or larvæ in decomposing discharges, and in the tropics wounds should always be protected as well as natural orifices discharging pus or fetid material. Larvæ of special flies may develop in the nasal cavities, the ear, vagina, urethra, skin or in the intestine, and the fly *Wohlfartia magnifica* may deposit its eggs in the conjunctival sac with serious consequences. Two chief varieties are distinguishable—the dermal and the intestinal.

The Screw Worm (*Cochliomyia macellaria*).—This fly, common in most of tropical and subtropical America, measures 9 to 10 mm. in length and is distinguished from the ordinary blue-bottle by the three black, linear, dorsal marks on its thorax. It lays its eggs upon foul wounds, the larvæ hatching in a few hours, and when mature measuring 2 to 3 inches in length. Super-

ficially the larva resembles a screw, being formed of twelve segments, each with a series of spines; it burrows into and feeds on the tissues, causing great destruction locally. When the nose is affected the larvæ often pass into the accessory sinuses, bore their way through the bones and even penetrate the skull, causing death by purulent meningitis. The vagina and ear may also be attacked and the middle ear destroyed.

Treatment.—PROPHYLACTIC.—This consists essentially in covering all wounds and discharging orifices, and avoiding sleeping in the open. Larvæ can be removed from wounds by ordinary antiseptic methods, and for nasal cases injection of chloroform, carbolic acid or turpentine may be used. Accessory sinuses may need to be opened.

THE MOSQUITO WORM (Ver macaque, beef worm) (*Dermatobia cyaniventris.* —This fly, common in Central America and adjacent parts of South America, measures 14 to 16 mm. in length, has a yellow head with brown eyes, a greyish thorax and dark metallic-blue abdomen. The eggs somehow become glued to the under surface of mosquitoes (particularly of the genus *Janthinosoma*), biting flies and even ticks, and in this fashion the larvæ are conveyed to the human skin where they invade the tissues via the puncture wound. A boil or warble results, containing a central opening through which the maggot breathes, discharges black excreta, and later escapes to the ground where it develops into a chrysalis and finally a fly. Cattle are also affected. Hadwen and Bruce have described a remarkable anaphylactic condition in oxen and sheep infected with larvæ of warble flies (*Hypoderma bovis*, *H. lineatum* and *Œstrus ovis*) characterised by dyspnœa, salivation, lachrymation, incontinent sphincters, vasomotor collapse, cyanosis and even death. This may be experimentally induced by injections of larval protein extracts or may result from natural trauma during life. Similar clinical features have not yet been recognised in man, though they probably occur.

Treatment.—Natives kill the larvæ with tobacco juice. The opening should be enlarged with a bistoury and the maggot removed with forceps; the cavity soon heals if treated antiseptically.

VER DU CAYOR OR TUMBU DISEASE.—This disease, common in Central and West Africa, is due to the larvæ of the Tumbu fly, *Cordylobia anthropophaga*, which is 8·5 to 11·5 mm. long, yellowish in colour, with black abdominal spots. The eggs are laid on the ground or clothing, and the emerging larvæ bore their way into the tissues by means of mouth-hooks. The first symptom is a pricking sensation, followed by the appearance of a boil or warble which commonly affects the buttocks, thighs and scalp of children, and often becomes inflamed. The larva takes about a fortnight to mature and then escapes via the central hole through which its fæces were previously excreted. Sometimes the cavity suppurates. Blacklock and Gordon demonstrated an acquired local skin immunity against cordylobia larvæ in guinea-pigs subjected to previous infection.

Treatment.—The aperture is enlarged if necessary, the maggot squeezed out, and the cavity treated antiseptically.

THE CONGO FLOOR MAGGOT.—The adult fly, *Auchmeromyia luteola*, is found throughout tropical Africa; it deposits its eggs on the floors of huts and outhouses, and when the larvæ have hatched out they suck the blood of people sleeping on the ground without causing pain. The larvæ crawl actively, are 15 mm. long and consist of 11 segments. The adult is orange-yellow in

colour, with longitudinal dorsal stripes on the thorax, and measures 10 to 12 mm. in length. Prophylaxis consists in sleeping on raised beds.

INTESTINAL MYIASIS.—Fly larvæ are common in human fæces; generally they are deposited after defæcation, but sometimes they originate from the intestine, the eggs being swallowed by man in food. Many species have been described, the genera *Sarcophaga*, *Fannia*, *Apiochæta* and *Anthomyia* furnishing the majority of examples. *Fannia canicularis* accounts for most cases in Europe. Gastro-intestinal symptoms may be mild or severe and include malaise, vomiting, diarrhœa and severe griping. General toxic features may include fever, rigors, headache, thirst and vertigo; even convulsions have been described. The bile ducts may also be implicated.

Treatment.—Castor-oil is generally sufficient, but thymol, filix mas, santonin and turpentine have also been recommended.

SPIDERS

Though spiders (Aranеæ) generally possess poison glands and inject venom into their prey, only a few species, mostly of the genus *Latrodectus*, are dangerous to man. Experimentally such venoms may slow the pulse and respiration, and produce tetanoid-like spasms and bronchial contraction in guinea-pigs. The red-backed spiders *L. mactans* in America, and *L. hasseltii* in New Zealand and Australia, and *L. geometricus*, *L. concinnus* and *L. indistinctus* in South Africa, where their colloquial name is "knoppie spider," produce local inflammation, œdema and numbness at the site of the bite as well as neurotoxic manifestations. In Peru the "pruning spider," *Glyptocranium gasteracanthoides*, causes local gangrene, hæmaturia and neurotoxic symptoms. Kobert noted oxyhæmoglobin and methæmoglobin in the urine of persons bitten by the "cross spider," *Epeira diadema*, and Sachs found in its venom a powerful hæmolysin. Probably many other spider venoms, like zootoxins generally, exert agglutinative, hæmolytic and neurotoxic effects. The tarantulas, on the other hand, give rise only to minor symptoms, though any spider with an effective biting mechanism may produce secondary bacterial infection. If seen early, treatment consists in immediate ligature, incision and suction, or washing out the wound with permanganate solution. Antiserum, if available, is effective. Morphine may be necessary to relieve pain, and injections of calcium gluconate (10 c.c. of a 10 per cent. solution) for laryngeal and muscular spasm. Intravenous saline and dextrose solution, and injections of nikethamide (coramine) and pituitary (posterior lobe) extract assist circulatory failure.

CENTIPEDES

The Scolopendridæ possess poison glands which discharge at the apices of a pair of specialised claws taking the place of the first pair of legs. The small centipede gives rise only to local manifestations associated perhaps with an erysipelas-like eruption, but the tropical species, *Scolopendra gigantea*, may cause around the punctures local necrosis and lymphangitis; headache, vomiting, fever, coma, and in children even death may follow. Treatment is similar to that of spider bites. Strong ammonia applied locally is useful.

SCORPIONS

Scorpions possess paired poison glands in the post-anal segment of the spined tail; this is thrust forward into its prey which is held in position by the formidable pedipalps. Scorpions in the tropics not infrequently kill children, and occasionally adults, and several species of the genus *Buthus* and *Centruroides*, as well as *Euscorpius italicus*, *Tityus bahiensis* and *Centrurus exlicauda*, etc., are much feared. The bite is most painful, and toxic symptoms may include fever, sweating, vomiting, diarrhœa, muscular cramps, trismus, stiffness of the neck, muscular paresis, respiratory failure and coma. Secondary bacterial infection is not uncommon. Acute abdominal symptoms due to hæmorrhagic pancreatitis have been recorded in Trinidad, and pancreatic cyst is regarded as one of the complications of scorpion poisoning there. Local treatment may be instituted as for spider bite, and the immediate application of strong ammonia or a local injection of cocaine and adrenaline relieves the pain. The intravenous injection of specific antivenene (5 c.c. for children and 10 c.c. for an adult), prepared by inoculating scorpion venom into horses, has greatly lowered the mortality rate amongst children in Egypt and South America.

G. Carmichael Low.
N. Hamilton Fairley.

E. DISEASES DUE TO SNAKES AND POISONOUS FISHES

SNAKES

Ophidiasis or snake poisoning results from the inoculation of venom by snakes of the families colubridæ or viperidæ; non-poisonous species occasionally cause death through septic infection following their bites.

Ætiology.—Snakes are carnivorous, and Alcock and Rogers showed that even non-poisonous species may have poisonous saliva. The venom is simply a specialised secretion of the parotid (poison gland) utilised in killing and digesting prey, while the fangs are modified maxillary teeth anteriorly grooved in the colubridæ, and completely canalised in the viperidæ. The biting mechanism is vastly superior in the vipers since the fangs are longer, and capable of considerable forward rotation, whereas in the colubrines they are generally shorter and more fixed. In biting, the snake strikes with great speed, opens the jaws, rotates forward the fangs, snaps the jaws together and ejects its venom from the poison gland via the duct and fang into the tissues in one almost instantaneous movement. The vipers withdraw immediately after biting. The colubrines often hang on to the bitten part and may need to be forcibly evulsed: to inject venom effectively they must have the lower jaw fixed, and though their venoms are more poisonous the yield is, as a rule, considerably less than that of the vipers. The toxic action of

venoms is mainly dependent on (*a*) proteolytic enzymes, (*b*) phosphatidases and (*c*) neurotoxins. The proteolytic enzymes, so well represented in viperine venoms, digest the tissues and damage the vascular endothelium (hæmorrhagin), leading to the escape of blood and the liberation of histamine which causes extensive local œdema and gives rise to symptoms of cardio-vascular failure (Kellaway). The coagulant properties of venoms are due either to a direct coagulation of the fibrin by the venom or to the conversion of prothrombin into thrombin (Eagles). The phosphatidases cause hæmolysis and also directly affect the heart and circulation; the acceleration of venom hæmolysis by lecithin is attributed to the transformation of lecithin into lysolecithin, which is itself actively hæmolytic. The neurotoxin formed in colubrine venoms has a strong peripheral effect, paralysing the sensory, proprioceptive and motor nerve endings. Paresis of the musculature is due to the curare-like action on the motor endings and a further direct action on the muscle itself (Kellaway).

Pathology.—In colubrine bites there is a congestive mode of death from peripheral respiratory failure, associated with fluid blood, a dilated right heart, and congestion and œdema around the fang puncture. In fatal viperine bites there is hæmorrhage, thrombosis and digestion of tissue locally, associated with a spreading gelatinous œdema resembling "red currant jelly," which sometimes involves the subcutaneous tissue of the whole limb; multiple hæmorrhages are found in the viscera, serous membranes, etc. Ante-mortem clotting is present in small animals, but not in man where the blood is fluid unless, as rarely happens, the fangs enter a vein: death results from cardiac failure, peripheral circulatory failure, secondary hæmorrhage, or septic infection and local gangrene.

Symptoms.—The clinical picture depends on the quantity and quality of the venom injected. Symptoms appear generally within 10 minutes to 2 hours after the bite, nausea, faintness and vomiting being characteristic early manifestations. Cardio-vascular shock follows both colubrine and viperine bites; paretic features predominate in the former, and general hæmorrhagic manifestations in the latter. In colubrine bites the fang marks are not always visible, and pain and local swelling are minimal; these features, however, are marked in the case of viper bites, which show in addition much hæmorrhagic oozing. Histamine shock accounts for the cold extremities, blanched, white skin, low blood pressure, vomiting, rapid thready pulse and extreme prostration. Psychical shock is sometimes an added factor, and may produce a somewhat similar picture in terrified natives bitten by non-poisonous snakes. In the earlier stages in colubrine bites the muscular weakness, ataxic gait and blurred speech may produce a picture simulating alcoholism, and diplopia, ptosis and blunting of sensation are not infrequently added; later there is inability to swallow, the tongue appears swollen, saliva dribbles from the mouth, the breathing, which was at first stimulated, becomes shallow and slow, and in fatal cases cyanosis, coma and convulsions of asphyxial origin ensue; the respirations may become costal in type and death occurs from peripheral respiratory failure. Hæmorrhagic extravasations (viperidæ) may lead to cutaneous petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia and melæna. In the early stages the gums may ooze blood and the urine contain red corpuscles.

Complications.—Blunting of the cough reflex and paresis of the muscles

of deglutition may be followed by insufflation pneumonia. After krait bites the anterior-horn cells of the cord may fail to recover or an acute ascending paralysis has been recorded some 10 days later. With viperine poisoning, local suppuration and gangrene sometimes necessitate amputation.

Course.—Death may occur within 20 minutes or many days later from complications. As a rule colubrine cases surviving for 3 days recover.

Diagnosis.—Generally this is not difficult, but cases may need to be differentiated from alcoholism and the bites of non-venomous snakes and scorpions. The grooved or canalised anterior fangs in the upper jaw make identification of a poisonous snake easy.

Prognosis.—This depends on the amount of venom injected, the efficacy of local treatment and the availability of specific antivenene. Even with really deadly snakes, factors such as clothing, inefficient biting or a poor venom yield may prevent a lethal dose being injected, and this fact accounts for many extravagant claims regarding the value of weird cures. Most first-aid measures are useless since the ligature is applied ineffectively or too late, and once a lethal dose of venom has been absorbed into the circulation, antivenene given intravenously is the only measure that will save life.

Treatment.—PROPHYLACTIC.—Snakes bite man more often by accident than design, and in snake country a little knowledge and common sense regarding the natural habits of the ophidia, the use of lanterns in walking along roads at night and the wearing of strong boots and leggings would greatly lessen the incidence of snake bite. Every second case is bitten below the knee.

CURATIVE.—Only two methods of treatment are of recognised value after a lethal dose of venom has been injected into the tissues: (1) Immediate ligature which delays absorption of venom, followed by such local measures as incision, excision, suction, or the injection of chemicals, the object of which is to remove or destroy inoculated venom before a lethal dose can be absorbed; (2) the intravenous injection of specific antivenene. By temporarily prolonging life, effective ligature may enable antivenene to be given in otherwise fatal cases.

Local Measures.—In sheep bitten by the tiger snake (*Notechis scutatus*) the absorption time of a lethal dose proved to be only 2 minutes (Fairley), so to be effective a ligature must be in position at the earliest possible moment. Pressure must be applied over a single bone proximal to the heart, *i.e.* over the femur in foot and leg bites, and over the humerus in bites on the hand and forearm; in finger and toe bites a boot lace may also be tied at the base of the implicated digit. Complete stasis of the circulation has to be attained as judged by blanching of the nails and failure of incisions to bleed. Thick rubber tubing ($\frac{3}{8}$-inch) is an ideal tourniquet, but in the field, strips of clothing, loosely knotted and twisted with a stick, are effective, and every 20 minutes the tourniquet may be loosened for 30 seconds to flush the limb with blood. After ligature the skin should always be wiped clean or washed, otherwise incision and scarification may lead to absorption of venom deposited and dried there (Ferguson). Scarification with or without the application of permanganate crystals is not effective, and mere incision is of doubtful value; it should be combined with suction either by the mouth or preferably with a breast pump or a Bier's suction glass. Excision of the bitten area and washing with permanganate solution, followed by mechanical suction is the best local treatment, and is the only one available where ligature is inapplicable as in

body bites. Polyvalent antivenenes are now available for cobra and Russell's viper in India, for the viperidæ and colubridæ of Africa, for the more deadly snakes of South America and for the crotalinæ of the United States. In Australia there is a monovalent antivenene for the tiger snake. The dosage varies, but antivenene must always be given intravenously as early as possible, and in colubrine bite is effective up to approximately two-thirds of the death time (Acton and Knowles). No case is too ill to receive it and even the most severely paralysed cases may recover; such patients must be carefully watched, as paralysis may reappear and further injections be necessary. In viperine bites it is less effective, and must be given in full dosage at the earliest moment. Infiltration of the tissues with antivenene in the vicinity of the bite may be useful (FitzSimmons). *General Measures.*—Patients must be kept warm and at rest. Black coffee and sal volatile may be given early, and injections of cortin, adrenaline or pituitary (posterior lobe) extract and of reconstituted plasma, followed by isotonic dextrose (5 per cent.), administered for circulatory shock. Nikethamide (coramine) has value as a respiratory and circulatory stimulant. Artificial respiration may prolong life, and it is important in cases with pharyngeal paresis to swab out the throat and keep the head low when the patient vomits; food should be withheld, and, if necessary, fluid given through a stomach-tube.

POISONOUS FISHES

In tropical waters casualties from poisonous fish are not infrequent. The effects of jelly-fish stings vary with different species; many are harmless, others produce local features such as urticaria, œdema, marked itching, burning and erythema, sometimes followed by vesicular dermatitis or actual sloughing and ulceration. Systemic symptoms may follow rapidly and include lachrymation, coryza, muscular pains, constriction of the chest, dyspnœa and cardiovascular shock. Deaths have been reported.

Fish of the genus *Muræna* bite with their powerful, grooved teeth down which poison from the venom sac enters the tissues; many harmful species are known, and their venom may have a depressant action on both the cardiac and nervous systems.

In other fish, such as the sting-rays, there are barbs in the dorsal fin or elsewhere connected with poison glands and these may produce not only severe inflammation locally, but neurotoxic features. Tetanus organisms may simultaneously be inoculated. Certain species of *Trachinus*, such as *T. draco* found in the Mediterranean, and of *Scorpæna*, such as *S. scropha* inhabiting tropical waters, are particularly dangerous, causing excruciating pain and local irritation, œdema, paralysis of the part, collapse, dyspnœa, delirium and even death within 24 hours. Septic infection may follow. Local treatment as for snake bite should be adopted. Infiltration of the tissues with procaine hydrochloride (novocaine) (2 per cent.) is often advisable for relief of pain, and morphine also may prove necessary.,

SECTION V

DISEASES DUE TO PHYSICAL AND CHEMICAL AGENTS

CAISSON DISEASE

Synonyms.—Compressed Air Illness; Divers' Paralysis.

Definition.—Caisson disease is the name given to a series of phenomena which may result in any living animal upon return to a normal atmospheric pressure after exposure to an air pressure which must exceed 18lb. to the square inch above mean atmospheric pressure. These phenomena occur the more frequently and severely the greater the air pressure, and in direct proportion to the length of time of exposure to the high air pressure, and the more rapid the return to a normal atmospheric pressure. They are caused by the saturation of the living tissues with nitrogen at high atmospheric pressure which, on too rapid return to lower atmospheric pressures, boils within the tissues, and this liberation of bubbles of nitrogen causes tissue disruption and destruction on the one hand, and gas emboli on the other. The major capacity of fat to hold nitrogen in solution causes the liberation of nitrogen bubbles to occur most readily in the fatty tissues, and this occurs more easily in those parts of the body where the blood supply is less abundant, and therefore the rapid return of the excess of nitrogen to the atmosphere by solution in the blood stream less easy. For these reasons the white matter of the nervous system, composed as it is of fatty substance, and particularly those parts of it which are less liberally supplied with blood, such as the white matter of the lower dorsal spinal cord, is the most common site of gas liberation. The joints and also their surrounding structures, which are lowly vascularised, are also common sites of the lesions, as are also the subcutaneous tissues of fat subjects, on account of the high solubility of nitrogen in the fat.

These phenomena occur only upon decompression, and are always preventable if adequate means be adopted (1) to limit the time of exposure to very high atmospheric pressures, so that high degrees of tissue saturation with nitrogen shall not occur, and (2) to regulate the return to normal atmospheric pressure by graduated decompression, in such a way as to prevent boiling of nitrogen in the tissues. They are curable, after they have appeared, by immediate recompression followed by very gradual decompression. Exposure of the living animal to very high atmospheric pressures may be associated with most serious and usually fatal results, which occur before decompression, and which are due to over-saturation of the tissues with oxygen, death resulting from oxygen poisoning.

Ætiology.—This disease made its appearance in the middle of the nine-

teenth century, when the invention of Siebe's diving dress and of subaqueous chambers made it possible for subaquatic engineering and marine salvage to be performed under high atmospheric pressures. The men work in a pressure of air, which just exceeds the hydrostatic pressure of that depth of water which extends from the working position to the surface, and the pressure is produced and maintained by pumps and regulating apparatus. Workmen reach the working face of the caisson by passing from the normal atmosphere through a series of chambers with airtight doors, in which the air pressure is raised by rapid stages, until the high pressure of the working face is reached. They leave through the same chambers, the air pressure being lowered for some space of time in each as they pass through. This process is termed " compression " and " decompression," or " locking in and out." The diver is compressed as he slowly descends by an increasing air pressure from his pump, and is decompressed as he ascends much more slowly, this compression being regulated by an automatic valve in his helmet which retains the air pressure until it exceeds that of the water pressure outside. Caissons are worked under a much lower pressure than that at which divers can work ; but the working shifts are much longer, whereas the diver at great depths remains down only a very short time. Roughly speaking, each 33 feet of water produces a pressure of 15lb. to the square inch (5½ fathoms). Caissons are usually worked at a pressure of below 35 lb. and in 6- to 8-hourly shifts, but they have been successfully worked at a pressure of 45 lb. with 2-hourly shifts, and at 50 lb. with 1-hourly shifts. Divers frequently work at 20 fathoms (53 lb.), and the record depth and pressure reached has been 210 feet (95 lb.).

During compression no trouble is experienced beyond discomfort in the ears and rarely perforation of the membrane tympani, from disparity of air pressure in the middle ear. This the workmen avoid by opening the Eustachian tubes with an act of swallowing or yawning ; but it must be remembered that no person suffering from Eustachian catarrh should be allowed to enter the air locks. Under high atmospheric pressures combustion proceeds more readily, a candle when lighted burns away furiously, and a pipe bursts into flame with each draw. The workmen find that they can work more easily and with less fatigue.

The symptoms of the disease become manifest upon return to a lower atmospheric pressure, and directly in proportion to the suddenness of return to such pressure. If the return to a normal atmospheric pressure from a high and prolonged pressure be sudden, there may be a liberal escape of bubbles of nitrogen gas in the blood and in the tissues. The presence of the nitrogen may sometimes be felt as gas crackling underneath the skin or subcutaneous emphysema.

When the return to a normal atmospheric pressure is more gradual, the nitrogen may have time to escape from the blood and from most of the tissues by diffusion through the lungs, but in those tissues which are relatively less vascular, and from which, for that reason, interchange of gases by means of the blood stream is slow, or in these tissues in which nitrogen is especially soluble, such as the fats and myelin of the nervous system, the nitrogen is liable to escape in the form of bubbles, and to the mechanical effects upon the tissues in which the boiling of the nitrogen occurs, the symptoms of caisson disease are due.

That part of the nervous system which is least vascular, namely the four lower dorsal segments of the spinal cord, is the most common region for the lesions to occur, while the joints and peripheral nerve trunks are often affected.

Massive escape of gas may occur into the blood stream, and the heart has been found distended with gas after death in rapidly fatal cases. A similar escape of gas into the intestines may produce severe and even fatal abdominal distension. It is doubtless one of the causes of the abdominal pain, nausea and vomiting which are common symptoms of compressed air sickness.

The liberation of these gases, and therefore the occurrence of the compressed air disease, depends directly upon these factors—(1) the amount of pressure to which the living animal is exposed; (2) the length of time of exposure to the high pressure; and (3) the rapidity with which a return is made from the high pressure to normal atmospheric pressure. For example, the malady never occurs after short exposures, such as 15 minutes at a pressure of 45 lb., or 2 minutes at a pressure of 75 lb., even though decompression be as rapid as possible, for these periods are too short to allow of nitrogen saturation of the tissues. It is for this reason that compressed air sickness is so much less common in divers, who for the most part work for very short times only at high pressures, and so much more common in caisson workers, who work for many hours at a stretch at a pressure of from 30 to 40 lb.

There is one other factor which must be carefully borne in mind, and that is the amount of fat present in the body, which, from its nitrogen dissolving qualities, greatly increases the tendency to nitrogen boiling within the tissues if it be present in large amount. It has been shown experimentally that fat animals succumb to the disease while lean ones escape, and experience has shown the necessity of excluding fat workmen on account of their liability to the malady.

The disease is obviously always preventable, firstly by shortening the periods of exposure according to the height of the pressure so as to obviate nitrogen saturation; and secondly by arranging that such a graduated and prolonged return to normal pressure be made, as will prevent any possibility of nitrogen boiling, the slow return to normal pressure allowing of the nitrogen desaturation of the tissues without bubble formation.

It is quite safe, and does not produce any ill effects whatever for a man to breathe pure oxygen for as many as 6 hours at a time. This has been proved by the use of the Siebe-Gorman life-saving dress for rescue work from choke damp in mines. Beyond a certain limit of pressure, however, oxygen becomes poisonous. Highly compressed air causes rapid toxic effects in proportion to the partial pressure of the oxygen. It tends to cause direct death of the tissues. At lower partial pressures it has a convulsant effect, and at still lower pressures produces congestion of the tissues and especially of the lungs, which may present consolidation and all the signs of acute pneumonia, however slowly and carefully decompression has been accomplished. The limit of safety so far as oxygen poisoning is concerned is 10 atmospheres, or 300 feet of water. Neither divers nor caisson workers ever work at anything like so high a pressure.

The essential feature on post-mortem examination is the presence of bubbles of nitrogen in the tissues or bulky collections of nitrogen within the

organs, as in the heart or in the intestines, and the results of the associated tissue disruption and air emboli. When it is considered that the mass of blood constitutes about 5 per cent. of that of the whole body, and that the capacity of the tissues in a thin subject is thirty-five times that of the blood, the ratio being much higher in a fat subject, since fat will dissolve five times as much nitrogen as will any other tissue, the presence of bubbles in the tissues, and especially in the fatty tissues, will readily be understood.

The bubbles form first in the venous blood and in the fatty tissues, where they grow by accretion and cause tearing of the tissues, while air emboli and subsequent necrosis are common. Hundreds of bubbles have been counted in the spinal cord, and these are much more numerous in the white than in the grey matter. Collections of nitrogen may be found in the subcutaneous tissues, and may cause palpable crackling. Bubbles of gas are not uncommonly found in the liver cells. Occasionally similar lesions are found in the brain or in the eye, and in fact may occur in any of the tissues. In every fatal case which has been adequately examined patches of necrosis in the dorsal region of the spinal cord, with the usual secondary degenerations, have been found.

Symptoms.—The symptoms may be first manifest during the process of decompression, when the latter is rapid, and from a high pressure. More often the signs of the malady appear soon after a normal pressure is reached, while not infrequently they do not present themselves until an hour or more has elapsed. In slight cases headache, giddiness, diplopia and faintness may occur, and these symptoms pass off soon and leave no trouble. Severe and important symptoms occur in the following order of frequency: (1) pain in the extremities or trunk, commonly called by the workmen "the bends" from the position in which the painful limbs are held; (2) pain in the epigastrium, sometimes accompanied by nausea, vomiting and abdominal distension; (3) paraplegic paralysis which usually involves motor, sensory and sphincter functions, and extends as high as the ninth dorsal segmental level; (4) headache, vertigo and coma; (5) sudden death; (6) hemiplegia or monoplegia of cerebral origin.

The pain in the limbs is of a neuralgic character and is referred to the joints, which are kept in the semiflexed position, any attempt to straighten them causing great pain. The pain may come on gradually, or suddenly, and may be slight and transient, or severe and persistent. It is often intolerable. The knees, ankles and hips are the most frequently affected; but sometimes the joints of the upper extremities, or of the back and especially of the lumbar region, may be affected. Epigastric pain is common, and unless quickly relieved by recompression is followed by nausea and vomiting.

The paraplegia usually has its upper limit in the lower dorsal, but it may reach the cervical region and involve the arms. It comes on rapidly, and involves motor, sensory and sphincter functions. It may be of any degree of severity from a slight and transient effect to a complete and permanent loss of the functions of the spinal cord. The paraplegia occurs with increasing frequency and completeness in proportion to the degree of pressure and the length of exposure to its influence. It occurred in 61 per cent. of 119 cases in the St. Louis bridge caissons, which were worked at plus 50 lb. of pressure, and among these there were 14 deaths. There is no general relation between the pain and the paralysis, as either may occur without the

other, and it seems, therefore, that the pain is due to a peripheral lesion and not to the lesions of the spinal cord. It is an interesting fact that the peripheral pains may persist in severe degree, even when there is total loss of pain sensibility from the spinal cord lesions.

Course and Prognosis.—The duration of the attack may vary within very wide limits. The severity of the initial symptoms, and the immediate application of appropriate treatment, are the all-important modifying factors in the prognosis. The attack may last for a few hours only, or it may continue for days. The paralysis may recover in a few days, or it may last for months and may never recover. Death occurs only in cases which have severe initial symptoms, and except when occasioned by complications such as cystitis and bed-sores it usually takes place shortly after the attack.

Treatment.—PROPHYLACTIC.—Since the malady is due entirely to nitrogen saturation of the tissues, and the subsequent escape from solution of this gas into the tissues during a too rapid return to normal pressures, it follows that the malady can always be prevented by adopting suitable period lengths for compression. In the first place, the malady never arises from compressions below plus 18 lb. to the square inch, or roughly 40 feet of water, and those who work at such a pressure may do so for long hours and return to a normal pressure rapidly, and without any risk. At higher pressures the working shifts must be shortened as the pressure gets higher. The shifts should be not longer than 6 to 8 hours at a pressure of 30 to 35 lb., or 3 atmospheres; 2 to 3 hours at a pressure of 45 lb., and 1 hour only at a pressure of 50 lb. At higher pressures than this, which are only encountered by divers, a few minutes' exposure is allowed only.

Compressed air sickness never occurs if the return to the normal atmospheric pressure be sufficiently slow. Animals can be exposed to very high pressures, short of those causing oxygen poisoning, with impunity, provided they be decompressed slowly enough. This decompression is carried out in the case of the diver by raising him to various levels in stages, and letting him remain at each stage a longer and a longer period as the surface is approached. In the case of caisson workers a series of air-locked chambers is provided in which the air pressure is lowered in stages, the men remaining longer and longer at each stage as they approach the normal pressure. The important fact in connection with decompression is that the absolute pressure can always be halved forthwith without any risk. In the first air lock on leaving the working face of a caisson, for example, the pressure is at once reduced to one-half that of the working face, and in the remaining air locks the pressure is reduced by stages until zero is reached.

Leonard Hill has shown experimentally that it is always safe to lower the pressure to plus 20 lb. by gradual decompression during the space of 10 minutes, then to wait at that pressure for 2 hours, and then bring the pressure to zero by gradual reduction in 10 minutes. The Admiralty rules for divers require that a diver working, say at 140 feet shall be first raised straightaway to a depth of 50 feet where he waits 10 minutes, then to 40 feet for 10 minutes, 30 feet for 20 minutes, 20 feet for 30 minutes, 10 feet for 35 minutes, and then he leaves the water abruptly.

The difficulty and danger is the tendency on the part of the workers to curtail these weary waits, and get away from work as soon as possible. It is important that all fat subjects, and all those who have shown a susceptibility

to compressed air sickness, and all those not in absolutely sound bodily health, shall be excluded from working in highly compressed air.

CURATIVE.—It was early discovered by the caisson workers themselves that the only remedy for the malady was to re-enter the high-air pressure. A recompressing apparatus in the form of a medical air lock is now supplied at all caisson works, and on all ships engaged in deep salvage. On the appearance of any symptoms the worker is placed in the compressing room and the pressure is run up to the full pressure at which he has been working, when it is usual for the symptoms to ameliorate rapidly or disappear. After the recompression the decompression must be carried out very slowly, for the bubbles once formed in the tissues are not easy to get rid of, though they may be kept at a small size by the pressure. Cases apparently at the point of death with cyanosis and coma have many times been completely recovered in a few hours by recompression. When symptoms have appeared, the decompression should take at least 5 hours. Caisson workers and divers should sleep and live close to the medical air lock that they may be near aid during the first hours following decompression. The paralysis when once established is to be treated upon ordinary lines.

ANOXÆMIA

Definition.—A series of phenomena which result in the living animal from deficiency in oxygenation of the tissues in the absence of carbon dioxide retention.

Pathology.—The condition is directly referable to lack of oxygen and lowered internal respiration. Anoxæmia is divided into three classes, with widely differing causal mechanisms:

1. *Arterial anoxæmia.*—This is due to a deficiency in the oxygen content of the arterial blood, the oxygen-carrying power being normal and the carbon dioxide discharge unhindered. It is apt to appear whenever the oxygen content of the arterial blood falls below the normal limit of 94 per cent. of its total capacity, and it may or may not be associated with cyanosis. It is the usual result of breathing a rarefied atmosphere in which the partial pressure of oxygen is lowered, and in this connection is known as "mountain sickness" or "altitude sickness" when heights approaching 20,000 feet are reached. The characteristic phenomena can be produced at will by respiration within a partially exhausted chamber, and they can be obviated at high altitudes by adequate oxygen addition in respiration. Arterial anoxæmia is also present to some extent in those pulmonary diseases in which there is damage to the respiratory epithelium, obstruction to the air passages and when prolonged shallow breathing occurs, as in pulmonary œdema, emphysema and pneumonia, and in these conditions oxygen addition is valuable if its administration can be very prolonged.

2. *Stagnant or passive anoxæmia.*—This results when, on account of some fault in the circulatory mechanism, the passage of the blood through the tissues is too slow to provide for adequate oxygenation. It is the common happening in the circulatory failure of cardiac disease. There is here no fault with the oxygen content of the arterial blood. The oxygen saturation of the venous blood falls lower than 65 per cent. of the normal, and the

normal difference between the oxygen saturation of the arterial and of the venous blood, which is 20 to 30 per cent., is exceeded, and there is always cyanosis, which appears when the reduced hæmoglobin content reaches 40 per cent. of the total hæmoglobin. Since the arterial blood oxygen content is not at fault, oxygen administration is useless to relieve this condition.

3. *Anoxic anoxæmia.*—This results from a deficiency in the oxygen-carrying power of the blood, either by reason of deficient hæmoglobin content, as in the anæmias, or by fixation of some of a normal hæmoglobin content, as methhæmoglobin, sulphæmoglobin, or carbon monoxide hæmoglobin. In the anoxic varieties, cyanosis does not occur, however severe the anoxæmia, for the reason that cyanosis only appears when 40 per cent. of a normal hæmoglobin content exists as reduced hæmoglobin. Therefore, an anæmic patient with 50 per cent. hæmoglobin would require 90 per cent. of the total hæmoglobin present to be reduced for the appearance of cyanosis. Oxygen administration is of no avail in anoxic anoxæmia.

Altitude Sickness; Mountain Sickness.—There is considerable difference among individuals as regards liability to the appearance of symptoms at low atmospheric pressures, some suffering earlier and more than others. The immediate effect of exposure to such pressures is to cause rapid concentration of the blood and therefore a relative increase of the ratio of the hæmoglobin to the volume. A 10 per cent. rise in the hæmoglobin ratio may occur after 20 minutes' exposure. This is in part produced by the rôle of the spleen in acting as a reservoir for the erythrocytes, which are discharged rapidly into the general circulation under these circumstances. This serves as a compensation for the oxygen-want of the tissues, and its occurrence is associated with a disappearance or amelioration of the initial symptoms of oxygen-want. In those who remain at a bearable high altitude many weeks, some degree of acclimatisation occurs, and this is associated with hyperactivity of the blood-forming organs and a true erythræmia. The anoxæmia produces a hyperglycæmia, and there is at first an alkalæmia from increased ventilation, which subsequently lessens.

Symptoms.—*Mental effects* occur most importantly when rapid ascents to high altitudes are made in aviation, and consist of a gradually increasing dulling of perception, of which the subject is usually unaware. There is an increasing inaccuracy and lethargy of mental functions with a tendency to torpor and loss of memory. The skilled photographic observer takes eighteen photographs upon the same plate, the observer throws his valuable notes overboard, the pilot makes for a wrong destination or goes to sleep, and the fighting scout forgets to go into action. On return to land a muddled and confused memory of what has happened during the flight is all that remains. Lesser degrees of this condition have led to great errors in judgment, foolhardiness, apparent cowardice and irresponsibility in military aviation. So insensibly does this mental paralysis come on and so deep may be its effect before its presence is realised, that in Tissandier's balloon ascent in 1875, all three aeronauts, though provided with oxygen apparatus, were paralysed beyond movement before realising the necessity for using it, and two of them lost their lives. Diminution of auditory perception becomes so great at high altitudes that the aeroplane engine becomes almost inaudible.

Respiratory effects.—At an altitude of 12,000 feet, nose-breathing ceases, and above this height the breathing deepens into hyperpnœa, which may

be most distressful and may be periodic. The dyspnœa is greatly increased on exertion and is accompanied by cyanosis. Even such acts as talking and using a pressure pump may greatly increase the dyspnœa.

Muscular weakness.—Accompanying the mental lethargy is an increasing condition of muscular weakness. The slightest exertion is hard work. The machine is difficult to fly at very high altitudes, and the marksman shoots badly, and the mountaineer becomes incapable of taking exercise.

Other symptoms which may occur are—(1) headache, which may be very intense and which is very usually met with in prolonged exposure to high altitudes, as in mountain climbing; (2) spasmodic gulping accompanying the hyperpnœa; (3) fainting on exertion; (4) vomiting; and (5) hæmorrhage in the form of epistaxis, both of which are rare; and (6) frequency of micturition, which is common.

The mental effects are most conspicuous in aviators who had to make prolonged flights at very high altitudes during the War of 1914–1918 before the regular use of the oxygen apparatus. The dyspnœa, headache and muscular effects have been most troublesome in mountain ascents where exertion is unavoidable.

Death has occurred only in balloon ascents to gain a great altitude, and it occurs very rapidly, and is preceded by general muscular paralysis. Glaisher and Coxwell survived 29,000 feet by a lucky chance after complete paralysis of the limbs had set in. Sivel and Croce-Spinelli died at a height of 27,500 feet, while Tissandier, who was with them, survived. The after-effects of exposure to high altitudes have been well described by Birley, who, after observing many flight landings after high patrols during the War of 1914–1918, writes: "The gait of the men on landing is unsteady and laboured. Reports are laboriously made out (there being a general disagreement as to what was seen and done). Tempers are short, every one looks and feels tired, and the idea uppermost in the mind is to lie down and go to sleep. Severe frontal headache is common; it may persist until the following day and at times proves incapacitating. Appetites are poor and spirits are depressed. It is easy to understand that a repetition of this kind of work over any length of time was rapidly productive of deterioration of mental and physical well-being."

Remarkable individual tolerance to anoxæmia occurs in some subjects, but this tolerance tends to disappear with repeated long exposure. Physical fitness and training increase toleration up to a certain point, whereas unfitness and especially digestive disturbances lower tolerance, and the latter are apt to induce vomiting.

Treatment.—Since the symptoms are due solely to lack of oxygen they can be entirely avoided by the use of a portable apparatus to deliver the necessary oxygen by all those who have to encounter an altitude of over 15,000 feet. Professor Dreyer's apparatus is portable, compact and satisfactory, and its essential feature is the regulation of oxygen delivery by an aneroid controlled valve, so that the amount of oxygen delivered varies in inverse proportion to the barometric pressure of the atmosphere surrounding the instrument and consequently in direct proportion to the altitude.

When symptoms have developed, the immediate treatment requisite is the cessation of exertion, the provision of oxygen if available and a speedy return to a lower altitude.

SEA-SICKNESS AND ALLIED CONDITIONS

Definition.—A disorder of the central nervous system produced by an unaccustomed and irrelative stimulation of the afferent organs which subserve the orientation and sense of movement of the body in space, namely, the eyes, the labyrinths, the splanchnic sensorium and the common sensorium of skin and muscles. This stimulation may occur when the body as a whole is subject to continuous movement which does not allow of continuous correct ocular and vestibular correlation of self and external objects, as in train-sickness and dancing-sickness, and more especially when it is subject to alternating movements which destroy the correspondence between the afferent impressions reaching the nervous system from those organs, as in sea-sickness and swing-sickness. The symptoms of this disorder are expressed as a feeling of spatial insecurity and visual disorientation, vertigo, diplopia, headache, anorexia, nausea and vomiting, pallor, lowering of blood pressure and prostration.

Ætiology and Pathology.—Animals are as liable to the disorder as is man. Early infancy is immune from the affection, since the orienting mechanism has not attained physiological activity; and old age is relatively immune, probably from lessening irritability of the nervous system. Individual hypersusceptibility and individual immunity are very common, and the readiness with which toleration is acquired by training varies greatly in different people. An attack of sea-sickness resembles closely an attack of migraine, and again it resembles acute cerebellar irritation, and again the symptoms which follow chloroform and ether anæsthesia and alcohol poisoning, for the reason that in all these conditions it is the nervous mechanism of orientation which is especially disturbed. The subjects of migraine are almost invariably particularly bad sailors and train travellers, and the symptoms of their attacks of sea-sickness and train-sickness often take the pattern of the migrainous attack. The importance of the factor of ocular disorientation is well shown by the fact that "sea-sickness" may occur in a susceptible subject when he is stationary but when the objects around him move in undulatory fashion, as from the movements of the waves when he is upon a pier and when he witnesses sea movements as a stage effect.

The precautions which tend to obviate sea-sickness are those which tend to eliminate or lessen the essential factors in its production. A position amidships where the angular movements are least, a supine decubitus which most protects the semicircular canals from stimulation, and which removes the muscular sense element, and in a cabin which moves more or less with the body, and therefore produces little ocular disorientation, is the one best calculated to avert or lessen the disorder. A gyroscopic cabin which removes all the factors except the "lift" and "scend" element is said to obviate the disorder even in the most susceptible subject.

There are many adjuvant factors which are important but not essential, such as apprehension from previous experience, cold, expectant attention, the smell of the ship, dyspepsia and the presence of others suffering from sea-sickness.

Symptoms.—The initial symptoms are a loss of the usual feelings of well-

being, accompanied by a vague feeling of cephalic, ocular and epigastric discomfort. Salivation, gaping and yawning follow, with irregularity of respiration, flatulency, pallor of the face, and a sense of squeamishness, as though at any moment vomiting might occur.

In the fully developed attack it is convenient to divide the symptoms into two groups—cephalic and gastric; but though in different subjects one or the other group may dominate the aspect of the attack, yet few persons suffer from the one group of symptoms to the complete exclusion of the other. The cephalic group comprises ocular distress, diplopia, which may be severe though transient, giddiness, headache, depression, and mental despondency and apathy. These may persist for a very considerable time after the patient goes ashore.

The gastric symptoms consist of nausea, retching and vomiting, which are often most violent and distressing, the vomit ultimately consisting of a thin, bile-stained fluid. There is complete anorexia, and in severe cases nothing can be retained in the stomach. Constipation is often obstinate.

The general constitutional effects of prolonged sea-sickness may be very severe. There is a general condition of collapse. Alternate heats and chills, with frequent chattering of the teeth and shivering, pervade the system; the eyes are dull, and may be bloodshot from straining; the countenance becomes shrunken, pale and perhaps greenish, inexpressive and dejected. The cardiac action is depressed, the blood concentrated, the body desiccated, and little urine is passed. The pulse and respiration are quickened, the skin is cold and either dry or clammy, the tongue is moist and coated, and both the breath and the urine are likely to contain acetone bodies. Hebetude is always marked, and in severe cases the mind may be utterly indifferent to the surroundings and no consecutive train of thought can be pursued. There is a general feeling of bodily soreness and weariness and a sense of exhaustion.

Course and Prognosis.—The symptoms usually subside rapidly when the voyage or other movement causing the condition is over, but sometimes both the cephalic and gastric symptoms persist for a time, and the patient is "good for nothing" until he has had a night's sleep. In persons taking long sea voyages, the symptoms usually lessen in a few days, reaction sets in with a return of appetite, and convalescence is complete within a week, but symptoms are liable to return with an onset of rough seas. Some persons, on the other hand, never lose the symptoms until the voyage, however long, is over, and these may be reduced to a piteous condition of bodily weakness, from which subsequent convalescence is slow. Death appears never to have occurred even in the most severe condition of bodily depression and starvation from sea-sickness. Apart from the prolonged convalescence which may be required in severe and long-lasting cases, there seem to be no harmful results from sea-sickness. It has been held to have a salutary effect upon subsequent health since ancient times. In pregnant women it does not have any tendency to cause miscarriage.

Treatment.—To avoid sea-sickness a susceptible subject should, for a few days before taking to the sea, eat sparingly, avoid alcohol and over-fatigue, take regular exercise and carefully attend to any condition of dyspepsia and constipation, and partake of a good wholesome meal some two hours before going on board. He should secure a berth amidships, lie

supine with the head low, and keep warm. Some persons find a closed cabin insufferable, and are better on deck in the open air. The administration of bromides some hours before sailing is often of signal service, and this will often lessen the cephalic symptoms when an attack has developed. Chlorbutol, (chloretone) (grs. 5) and phenobarbitone (gardenal, luminal (gr. 1) are also very valuable, both as prophylactics, when they should be taken just before sailing, and as remedies during the attack. Combinations of bromides and chlorbutol are very useful, and there is at least one patent remedy, of which the basis is monobrom-camphor and chlorbutol, which is very efficacious.

During the attack it is essential to keep warm and as quiet as is possible, and avoid any source of further irritation of the organs of orientation; to quiet the irritation of the nervous system with bromides and chlorbutol; to secure sleep, to which end barbitone or adalin is very useful; to prevent acidosis and to see that the patient is fed. With severe and prolonged vomiting, anorexia and prostration it may be difficult to secure these ends. Swallowing food must be insisted on, and the administration of very small perfectly dry meals, such as cold chicken and biscuit, will often break the anorexia and vomiting. A severe case should always be brought into the open air on deck after four days in the cabin. Acidosis should be combated by the alkaline carbonates. Alcohol and aromatic carminatives are sometimes valuable.

JAMES COLLIER.

ELECTRICAL INJURIES

Electrical injuries may be received from lightning-stroke, from accidental contact with high-tension conductors, or from judicial electrocution where this obtains.

The severity of the injuries sustained in any given case depends upon other factors than the voltage of the discharge received, and thus it is that fatal injuries may be received from currents of comparatively low voltage (120 volts), and survival may follow the reception of currents of higher potential. It is said that a current of 500 volts is commonly fatal, and that alternating currents are more dangerous than direct. Voltages of over 1000 are spoken of as "high tension." The quantity of the current is also of importance. A current of 100 amperes is dangerous, one of 500 is likely to be fatal. In judicial electrocution the victim is subjected to repeated discharges (4 to 8), each lasting some seconds (5 to 50), of alternately high and low potential (500 volts alternating with 2000).

Pathology.—In those who survive electrical injuries complete recovery is usual—though not invariable—and it is clear that the lesions found in the nervous system in fatal electrical injury can hardly obtain even in slight degree in non-fatal cases. We shall first describe the lesions found in fatal cases.

In death from lightning-stroke the head is invariably struck, and there is a localised effusion beneath the scalp, which may be differentiated from the effects of a blow by the absence of abrasion. The body surface shows burns of various forms—linear burns, arborescent burns, and severe localised

burns beneath any metal object which may have been carried in a pocket or worn on the person.

In the nervous system there are abnormal rents and fissures in the brain, the cerebro-spinal spaces are distended, the perivascular spaces enlarged, and the arteries at the base of the brain may show rupture of their muscular coats. In various situations the nerve cells show severe disruptive changes. In the past it has been assumed that these lesions are due to the passage of an electrical current through and over the body, but in a recent analysis of the circumstances of electrical injuries from the point of view of physical science Blake Pritchard has shown that this passage is inadequate to account for the nervous lesions, and that two factors are operative. These are the passage of current, and the charging of the body with electricity. It is the latter factor which alone is capable of producing the lesions found in the nervous system. The following brief summary is taken from Pritchard's account (*Lancet*, 1934, I. 1163).

If a man make contact with a conductor at high potential, or if he be struck by lightning, he will suddenly become highly charged with electricity. A current will pass through him only if he is in a position to lose this charge. If he is not insulated from earth the charge will pass rapidly through and over him, and will not accumulate upon him. This rapid passage will give rise to heating, electrolytic and mechanical effects, but these alone do not produce the lesions observed in fatal cases.

If he be more or less effectively insulated from earth, his body surface will become highly charged, and electrostatic forces will develop from the mechanical repulsion which is exerted between similarly charged particles or bodies. A charged body will be repelled from all similarly charged bodies, and all the constituent elements of the body which carry the charge will be repelled from one another. Thus it is that when more than one object is struck by lightning, they are flung apart; a man is flung several yards from a tree under which he has been standing; or two men simultaneously struck are flung away from each other; a parcel held by an individual struck is hurled out of his grasp, and also his clothes, belt and boots are burst and torn off him in fragments, and he may be stripped naked. Within his body the same disruptive forces are at work, and produce lesions in proportion to the rigidity and cohesion of the tissues. The charge upon his body surface will make each particle of the surface repel each other particle, the whole surface will tend to expand away from the body, and this sudden expansile force will pass inwards as a wave of decompression. In this way we may account for the characteristic disruptive lesions found in the brain.

It is probable, then, that the electrostatic effects play a determining part in the production of the nervous lesions, and that these in their turn are largely responsible for a fatal issue when this ensues.

The actual passage of the current has heating and electrolytic effects, and Pritchard has tried to assess the importance of these. In legal electrocution, where alternating currents are applied in the manner and of the strengths described earlier, it is possible to form a fairly precise estimate of the heating effects. The current probably passes chiefly in the body by the blood and cerebro-spinal fluid, as well, of course, as over the body surface, where it produces the characteristic burns. It is possible that currents of the orders used may cause a rise of temperature in the tissues

they traverse of as much as 60° C. In lightning-stroke, the rise is probably much less. The higher rise named is capable of severely damaging the nervous system, but not of producing the lesions seen in fatal cases. The electrolytic effects are probably negligible.

Another effect of the passage of current—as opposed to the charging of the body surface—is the violent and generalised cardio-vascular and skeletal muscle spasm found so constantly in the victims of electrical discharges. This spasm may persist for some time, and in fatal cases until death has ensued. The heart and muscular coats of the arteries are strongly contracted, the victim is pale and pulseless, and in non-fatal cases may so remain for as long as an hour while artificial respiration is being employed.

Symptoms.—Graphic accounts of the effects of lightning-stroke are given by H. A. Spence in his monograph, and are based upon an extensive experience in South Africa. When struck by lightning the individual may later have no recollection of the incident, but on the other hand may speak of receiving a tremendous blow on the head. Others have complained of intense visual or auditory sensations, of pain in the trunk and limbs, of giddiness, and so on. The subject is usually unconscious, pale and pulseless, and respiratory movements are suspended. Surface burns of varying severity and extent are seen, and examination of the scalp will reveal a localised swelling at or near the vertex, with no cutaneous abrasion. There may be powerful and generalised muscular spasm for a brief period and the limbs may be in flexion.

As respiration becomes re-established—either spontaneously or after artificial respiration—the subject may become restless and resistive, crying with the pain of muscular spasm. Later, he becomes drowsy, has headache, and for one or more days may not be fully alert.

This initial state of suspended animation and apparent death is common after lightning-stroke, but not so common, apparently, after accidental electrical injuries from contact with conductors. It may be necessary to carry out artificial respiration for as long as an hour before—in non-fatal cases—respiration becomes normally established.

After accidental electrical injury the degree of shock varies from individual to individual. It has been suggested that in sleep the injury is less severe than in the waking victim, but it is probable that the two main factors discussed earlier play a more important part in determining the severity of injury than matters of sleep, individual susceptibility, fatigue and old age, all of which have been thought to have some influence in this direction.

Recovery from the effects of electrical shock may, as we have seen, take several days, and in rare instances more or less permanent residual symptoms of a neurological kind may ensue. Thus, Spence records a case where memory remained defective, speech slow and gait unsteady, and one ear was permanently deaf. An immediate effect which has been described is profound weakness with sensory loss of the lower limbs, which may be blue and cold. This condition passes off gradually in the course of some hours. A progressive condition clinically resembling amyotrophic lateral sclerosis has been described by Panse as a rare sequel of electrical injury, and this factor has been invoked in connection with disseminated sclerosis and Parkinsonism when these have developed in the subjects of electrical injury. Attributions of this order should be received with caution. Of course, as after other injuries, traumatic neuroses may follow electrical shock.

Diagnosis.—Spence records instances in which the finding of a dead body has made it necessary to determine the cause of death. When this is due to lightning-stroke, the following signs are found. There is an effusion beneath the scalp without superficial abrasion, and streaks of "brushburn" will be found upon the body surface. The body will be more or less stripped of clothes. If a hat was worn, a hole will probably be found in it over the seat of the scalp lesion. Leather garments, boots and belts are burst. Of course, if the victim was hurled or flung down some other signs of injury caused in this way may be found.

Treatment.—When, as is commonly the case after lightning-stroke, the victim is unconscious, white and pulseless, artificial respiration must be undertaken at once, and persevered with for at least an hour before abandoning the patient. Even when respiration is first resumed, it may fail again and artificial respiration must be kept up until normal breathing movements are fully established. When consciousness is regained, the patient may complain of severe headache and of painful muscular cramp. The latter should be treated by massage. The usual restorative measures employed in severe shock may also be used, but the essence of treatment in severely shocked and unconscious patients is the carrying out of artificial respiration.

The superficial linear burns of lightning-stroke may smart if exposed to the air, and are best covered by ointment, but they usually heal without scarring. The deeper burns related to metallic objects carried by the victim, or to the points of entry and departure of the current in accidental injuries from contact with conductors, will sometimes require the ordinary treatment of burns according to their depth and extent.

The very rare residual neurological symptoms and disabilities may have to be dealt with according to their character and severity.

F. M. R. Walshe.

HEAT-STROKE AND THE EFFECTS OF HEAT

Under this heading are included those types of illness caused by exposure to a high atmospheric temperature. They are classified as—(1) heat exhaustion; (2) heat hyperpyrexia (heat-stroke or sun-stroke); (3) the gastric type of illness; and (4) the choleraic or gastro-intestinal type.

Ætiology.—*Exposure to high temperature.*—Cases commonly occur amongst those exposed to the sun in the hot seasons of a tropical climate; but the high temperature of the air in a dwelling, or the excessive heat to which stokers are exposed on board of ships, or, indeed, any prolonged exposure to a high atmospheric temperature, whatever its nature, may cause any of the types of heat-stroke. When the shade temperature reaches 110° F., danger occurs, and with each degree rise above this limit an increasingly larger number of cases results. The effect of heat exposure is cumulative in action, and it is a succession of hot days which is followed by a large number of cases of heat-stroke. A comparison by Willcox of the case incidence curves with the temperature curves in the Mesopotamian campaign indicated a delay of a few days in the rise of the former. An individual exposed to heat for one or more days may not be taken ill until the evening or early morning, when the temperature has fallen consider-

ably, the cumulative effect of the exposure gradually overcoming the body resistance. Since the temperature in the sun greatly exceeds that in the shade, exposure to the sun's rays is a very important exciting cause. In the hot seasons of tropical countries this danger is well known, and exposure to the sun is avoided as far as possible. It has not been shown that any rays of the sun other than the heat rays have a special significance in the causation of heat-stroke.

Climate.—Tropical climates in seasons when the shade temperature exceeds 110° are associated with the various forms of heat-stroke, and heat waves in any climate, if the temperature is sufficiently high, act as causes of illness. The absence of shade from the sun is an important factor, and heat-stroke is specially associated with hot climates of countries where flatness and absence of trees and vegetation are marked, as, for example, in Mesopotamia and the country round the Persian Gulf, and desert regions generally, as in the Sahara Desert in Africa. In countries where, during the hot season, there is little fall of the temperature at night, the danger from heat-stroke is increased.

Humidity of the atmosphere is an important predisposing factor. If this is high, heat loss is retarded, and there is greater liability to heat-stroke.

Stagnation of air.—Free currents of air promote the evaporation from the skin and protect by increasing heat loss. The great protective value of electric fans and punkahs in dwellings is due to this cause. It is important to remember, however, that when the temperature is very high, currents of hot air may do more harm than good, and for this reason, in tropical countries, houses provided with fans should be kept closed during the heat of the day, in order that the hot air may be excluded as far as possible. The "Kata" thermometer, introduced by Professor Leonard Hill, F.R.S., records the rate of heat loss from evaporation of a wet bulb, and is a valuable guide in estimating the dangers from heat-stroke in different situations, such as the wards of hospitals.

Dwellings.—Thick walls of non-conducting material, such as stone, brick, or dried mud are protective, and it is important that the roofs of dwellings should be thick, so as to keep out the heat from the sun's rays. A tent, even of double canvas walls and roofs, affords only poor protection.

Persons of any age are subject to heat-stroke if the exposure is sufficiently great. The case mortality is higher in those over 40. Race is a very important factor. The natives of tropical countries are rarely affected by heat-stroke, unless some complicating disease, such as malaria, is present. White races unaccustomed to tropical climates are specially susceptible to the effects of heat exposure. Exertion is an important predisposing cause. Heavy physical exertion in temperatures over 110° is very dangerous.

Predisposing diseases.—Any disease causing pyrexia, such as malaria, sand-fly fever, enteric and paratyphoid fever, typhus fever and small-pox, predisposes to heat-stroke.

Intercurrent diseases.—In a high percentage of cases the heat hyperpyrexia supervenes in the course of another disease, especially malaria. Cases of febrile disease may be suddenly complicated by hyperpyrexia if exposed to great heat, and special precautions are necessary to prevent this.

Pathology.—The symptoms of heat-stroke in its various forms all point

to an auto-intoxication. The effect of high temperature on the brain and central nervous system is to diminish its functional activity, and likewise the excretory organs, such as the liver and kidney, are undoubtedly impaired in their excretory power. In addition, owing to the effect of heat on the muscles and tissues of the body generally, there must be an increased production of toxic substances, due to protein katabolic changes. These factors all tend to produce a marked auto-intoxication, which explains many of the symptoms of heat-stroke. Indican is usually present in the urine in considerable excess, and is evidence of an auto-intoxication. Acetone and diacetic acid are not found in appreciable excess in the majority of cases, though in a small percentage they are present in moderate degree. The auto-intoxication cannot, therefore, be regarded as an acidosis. It has been shown by Dr. W. Cramer that beta-tetra-hydro-naphthylamine will cause hyperpyrexia in animals, and it is likely that substances having a similar action are produced as the result of the heat on the tissues. Suppression of sweating has been shown by Dr. K. G. Hearne to be an important factor in the hyperpyrexia cases, the paralysis of the sweat secretion by the intense heat leading to a rapid rise of body temperature. In hot climates, the administration of atropine may be followed by hyperpyrexia from a similar cause. Suppression of sweating does not explain the causation of the gastric and choleraic type of heat-stroke, nor of heat exhaustion. It has been stated that heat-stroke is due to a bacterial infection; but there is no recent evidence to support this view. In the Mesopotamian campaign a large number of blood examinations were made during life in cases of heat-stroke, but all gave a negative result.

Rigor mortis occurs early, and putrefactive changes set in within a few hours of death. Œdema and general hyperæmia of the brain and lepto-meninges occur, and the nerve cells in the grey matter show marked degenerative changes. Petechiæ occur in the skin and mucous membranes in severe cases. The right side of the heart is dilated, and venous congestion is marked in all the organs. Signs of intercurrent diseases, such as malaria and typhoid, may be present.

Prophylactic Treatment.—Adequate protective covering for the head by thick pith topees or good cork helmets is essential. Spinal pads for protection of the spinal cord are valuable. The clothing should be light and loose and not too thin. Hand-fans and umbrellas are of value. A large amount of water should be drunk by those exposed to great heat, as so much moisture is lost by the skin in regulating the body temperature. Salt (sodium chloride) should be taken freely with food, to compensate for the loss of sodium chloride by excessive sweat excretion. Alcohol should be avoided during the heat of the day. Constipation should be guarded against, as it predisposes to the effects of heat.

1. Heat Exhaustion

The onset is sudden, with weakness, giddiness, faintness and inability to walk. A mild pyrexia of 102° or 103° F. occurs, lasting 2 or 3 days. The pulse is rapid and weak, and some cardiac dilatation is usually evident. If early treatment is adopted, the symptoms quickly improve; otherwise, there is a great risk of the supervention of hyperpyrexia.

Curative Treatment.—This consists in removal from heat, rest in bed and the administration of aperients.

2. Heat Hyperpyrexia

The onset may be sudden, with rapid rise of temperature, coma and convulsions. In other cases, the onset is preceded by malaise, headache, restlessness and sometimes nausea or vomiting. Frequency of micturition and urethral pain may occur. The temperature is somewhat raised—to 100° or 102° F. or so—and the skin hot and dry. These premonitory symptoms may last for a few hours, sometimes as long as 48, when the temperature rises to 110° F. or more, and mental excitement and delirium supervene. Coma and stertorous breathing now occur, and the face is flushed and cyanosed, the conjunctivæ being congested. The pupils are commonly dilated in the early stages and contracted in the comatose condition. Parotitis may occur, and petechiæ of the skin may be present in severe cases.

Albumin is frequently present in the urine in small amount in acute cases. An excess of indican is usual, and in some cases acetone and diacetic acid occur. Fibrillary twitchings of muscles and convulsions usually result, and the breathing is frequently Cheyne-Stokes in character. Incontinence of urine and fæces occurs with the coma, and death rapidly results, unless the temperature is reduced. Marked cardiac dilatation, often associated with a systolic murmur, is present. Bronchitis and pulmonary congestion sometimes occur, and pulmonary œdema is a terminal event. In the acute stage the knee-jerk is almost always absent, and does not return until the symptoms have cleared up.

Defective articulation (anarthria) occasionally occurs as an after-symptom, and sometimes nystagmus, or squint, with diplopia has been observed. Multiple neuritis, with weakness and wasting of the extensor muscles of the legs, is a rare late complication. After the subsidence of the hyperpyrexia, a pyrexia up to 102° or 103° F. may persist for several days, and is due to the auto-intoxication present, no organism being found in the blood in the uncomplicated cases. For some weeks after the subsidence of the temperature there is great liability to a recurrence of heat hyperpyrexia, and the utmost care must be taken to avoid exposure to heat.

Sequelæ.—Cardiac dilatation may last for some days or weeks after an attack. There is a great susceptibility to heat for a long period after an attack, and headache may follow slight exposure, so that residence in a cool climate is advisable for some years afterwards. An abnormal mental condition, amounting in some cases to insanity, may result. Persistent nervous symptoms, the result of actual organic changes in the brain or cerebellum, may remain. The presence of the knee-jerks is a valuable prognostic sign; if they remain absent there is danger of a recurrence.

Curative Treatment.—The patient should be placed in cool surroundings and hydro-therapeutic measures immediately adopted. Spraying with ice-cooled water, the patient lying on a bed with a rush mattress, so that there is free circulation of air round the body, is the most convenient method. Ice should be applied to the back of the neck and head. Rectal injections of iced-cold water, to which about 1 per cent. of sodium chloride is added, are of value. Should the hyperpyrexia not quickly subside, or should it not

be readily controlled, an intramuscular or intravenous injection of a solution of quinine bihydrochloride, grs. 10 should be given. Blood film examinations should always be made immediately when hyperpyrexia occurs, and if these show a malarial infection the quinine treatment should be continued, daily injections being given for 3 or 4 days, and afterwards an oral course. Convulsions are best treated by a venesection of 10 to 20 ounces, and rectal injection of ice-cold water containing 120 grains of sodium chloride (common table salt) to the pint. In cases with convulsions it is not advisable to give intravenous saline after venesection, for the intravenous injection may cause recurrence of the convulsions. In some cases morphine hypodermically or inhalations of chloroform may be required. Cardiac failure should be treated by digitalin, strychnine, camphor in oil, nikethamide (coramine), adrenaline or pituitary extract hypodermically. Failure of respiration should be treated by artificial respiration, and oxygen bubbled through alcohol may be administered. Lumbar puncture is of value in the comatose condition, in order to relieve the excessive pressure in the cerebro-spinal fluid.

When the patient is able to swallow, as large quantities as are safely possible of physiological saline should be given. This may also be given by nasal tube.

Loss of sodium chloride is a marked feature of cases of illness due to the effects of heat. This should be administered in quantities of 12 to 20 grammes per day for several days.

3. The Gastric Type

In this insidious type of illness for several days the patient will suffer from restlessness and mental irritability, nausea and occasional vomiting. The face is flushed and the mouth temperature normal; but the rectal temperature may show a rise of a degree or two. The liver shows some enlargement, and the knee-jerks are lost. In many of these cases after 4 to 10 days' illness a sudden hyperpyrexia occurs, which is often fatal.

Curative Treatment.—This consists in keeping the patient at complete rest in bed and as cool as possible, free purgation, a lacto-vegetarian diet, and rectal injections of ice-cold water containing bicarbonate of soda, 60 grains and sodium chloride 120 grains to the pint, and the administration of 30 grains of sodium bicarbonate every 3 hours; by these means hyperpyrexia is avoided. Liquids should be taken freely by mouth, and sodium chloride in doses of 12 to 20 grammes daily should be given by mouth to replace the loss by sweating.

4. Gastro-Intestinal or Choleraic Type

In this form of illness the onset is sudden, and marked collapse is present. The temperature is raised to 100° or 102° F., and vomiting and diarrhœa occur. The face is pale, the skin clammy and the eyes sunken. The knee-jerks are lost. The stools are watery, and free from cholera organisms. Death usually occurs after a 3 or 4 days' illness.

Prognosis.—This is very grave.

Curative Treatment.—This consists in protection from heat, and the administration of normal saline subcutaneously or intravenously. The intra-

venous hypertonic saline treatment as advocated by Rogers, and described in detail under the article on Cholera (see page 121) should be given as soon as possible for the treatment of the collapse and loss of fluid. The administration of suitable cardiac stimulants hypodermically is advisable.

HEAT CRAMPS.—Attacks of heat cramps occasionally occur in persons who perform muscular exercises while exposed to high temperatures. The condition occurs in stokers on board ship, and in furnace workers. The muscular spasms occur in the calves, arms and sometimes the abdominal muscles, and are severe and very painful. They may last from 12 to 36 hours, and are followed by soreness and weakness. Deficiency of sodium chloride in the blood is the chief cause of the symptom. Doses of 10 to 20 grammes daily should be given well diluted with water or other beverage or food. Tablets of one gramme sodium chloride may be swallowed in doses up to 20 per day.

W. H. WILLCOX.

INJURIES FROM X-RAYS

Ætiology.—Within 3 months of the announcement by Röntgen of his discovery of X-rays in November, 1895, it became known that conjunctivitis could occur after some hours of exposure to irradiation. A year later erythema, swelling, and necrosis of the skin, alopecia, and chronic radiodermatitis were reported. In 1897 attention was directed to the acute constitutional symptoms. In 1902 a case of cancer was recorded following chronic ulceration caused by X-rays. The first death recognised as due to the action of X-rays occurred in 1914. In 1922 it was estimated that 100 radiologists had died from malignant disease due to their occupation. Deaths occurred among radiologists exposed to X-rays before the importance of adequate protection was realised, and unfortunately still occur.

So far nearly all the victims have been research workers, radiologists, laboratory assistants, technicians and nurses. Cases of industrial origin did not occur until later, because the use of X-rays in industry began later. Industrial workers, unlike professional workers, are often quite ignorant of the possible dangers of the apparatus used, so that industry is now, in respect to the use of radio-active substances, about where medical practice was in 1914. There is, however, no reason why the lamentable history of the pioneers in the medical field should be repeated. The human experiments have been made, the tragic results of carelessness demonstrated, and the measures necessary for adequate protection are known and available to anyone who cares to learn them.

X-rays may be used in industry for the detection of defects, cracks and blow-holes in castings, of defects in alloys from faulty mixture, of erosion in cables or gas cylinders, and of defects in reinforced concrete or in weldings. X-rays are also used to sort fresh eggs from stale, to reveal mineral adulterants in vegetable foods, and weevils in grain. For the examination of metals and all thick specimens very penetrating rays must be used.

Symptoms.—Injuries which follow a short single exposure, or perhaps several exposures, may vary enormously in intensity. In mild cases there is simply a transient reddening, lasting a few days and followed by scaling

and loss of hair. If the burn is deeper, blisters appear which may be serous or purulent, and the condition resembles that following a scald but is less acute and slower to heal. Sometimes the process, instead of disappearing in a few weeks, penetrates to the deeper layers of the skin and to the subcutaneous tissues, with the formation of a leathery slough, surrounded by a brawny indurated swelling with ill-defined limits. The process is exceedingly slow and obstinate, and has a tendency to progress and to resist treatment in a remarkable way. It is at times very painful.

In chronic X-ray dermatitis the changes in the hands begin round the base of the nails as a peculiar erythema and gradually increase. Transverse and longitudinal ridges appear on the nails, which become brittle, assume a characteristic dirty brown appearance, tend to separate from the matrix, and eventually thicken and form shapeless masses. The skin becomes uniformly red and atrophied ; small warts appear, increase in size and number and, when situated over the knuckles, crack and cause much pain. Later the dry thickened skin shows telangiectases, absence of hair, paronychia and ulcers which are slow to heal and prone to break down. The hair follicles and the sebaceous and sweat glands completely disappear in cases of long standing. The freedom of the palms of the hands may be due to the naturally thicker skin there, but the greater liability to exposure of the backs of the hands and fingers is probably the more important factor. The lesions are as a rule slowly progressive. Post-irradiation telangiectases, which have been regarded as compensatory for obliteration of the vessels in the corium, usually appear within 2 years, and sometimes in the absence of an initial erythema ; in some instances the interval between irradiation and the appearance of telangiectases is prolonged, even to 15 years. If exposure is continued the lesions may progress to involve the tendon sheaths and joints. There may be intense pain, of which the severity is out of proportion to the size of the lesions ; it is caused by the exposure of nerve-endings.

Squamous-celled carcinoma is almost always the form of malignant disease which has followed excessive X-ray exposure and long-continued X-ray dermatitis in man. Although most often seen in radiologists and manufacturers of X-ray apparatus, X-ray carcinoma may also occur in patients who have undergone treatment by X-irradiation. The interval between the onset of chronic X-ray dermatitis and the appearance of malignant disease varies from 3 to 27 years. The average of 35 cases was 7 years. The age incidence from 35 to 50 is comparatively early, that of ordinary carcinoma of the skin being between 55 and 58. The most frequent site of the growth, which is not uncommonly multiple, is on the backs of the hands and fingers, and the hand more exposed appears to be the one more severely affected, the left in radiologists and the right in those engaged in the manufacture of apparatus. Among radiologists carcinoma usually develops in an ulcer, less often in keratotic areas. The predominating symptom is pain, which may be constant and very severe, and has been ascribed to invasion of the terminations of nerves by the growth and to neuritis. Occasionally basal-celled carcinoma results from X-irradiation. In one case a basal-celled carcinoma of the scalp appeared 18 years after epilation for ringworm. A case has also been recorded of multiple basal-celled carcinomas on the trunk of a radiographer.

Constitutional symptoms only became prominent after the introduction of deep X-ray therapy, in which massive doses of deep penetrating rays were given. Severe constitutional symptoms may occur. They are nausea, uncontrollable vomiting, sometimes with hæmatemesis, diarrhœa, with the passage of blood, abdominal pain and distension, fever up to 104° F., restlessness, profound prostration, progressive cardiac failure, small rapid pulse and dyspnœa. When death has occurred it has usually taken place about the fourth day from the onset. Both animal experiments and necropsies of human victims show that the application of X-rays to the abdomen may result in necrosis of the intestinal mucosa. As long ago as 1905 unsuspected sterility was found in 18 persons who had for various periods been exposed to X-rays. The acute degenerative changes in the testes are followed by fibrous atrophy. Anæmia occurs in X-ray workers. After small doses of X-rays, the lymphocytes are first increased in number, then diminished. The red cells may also be increased at first, but anæmia sets in later and may become extreme. In patients who recover, the anæmia is slower to disappear than is the leucopenia. True aplastic anæmia does not occur.

Diagnosis.—The possibility of exposure to radium should always be excluded before attributing what appears to be aplastic anæmia in an X-ray worker to X-irradiation.

Treatment.—PROPHYLACTIC.—Within the first few months after their discovery it was found that X-rays were stopped more effectively by lead than by any other common metal. Hence lead for protection came into use very early. To-day lead, lead glass, lead rubber and lead bakelite are extensively used. Transparent lead glass windows in tube containers were first employed about 1900. At that time the need for protecting both operator and patient during radiographic exposure was very great, because low voltages were used, with consequent long exposure to a very soft and easily absorbed radiation. For example, to radiograph the spine required exposures up to 1 hour. That the radiologist was not more frequently affected by the scattered radiation of such exposures was due to the fact that during them he might retire to another room to see other patients. About 1903 there appeared a multitude of protective devices to be worn by the radiologist, including apron, jacket, gloves and goggles. This type of protection gradually reached its peak about 1914, when necessity threw caution to the winds, and the more elaborate devices gave place to means of protection which were built into the apparatus.

To-day there is international agreement as to the most effective methods of prevention. In Great Britain such methods have been widely adopted, and although they have no strictly legal recognition, powers of inspection and approval have been placed in the hands of the National Physical Laboratory. It is important that the industrial physician should plan measures for the protection of employees against the dangers of X-irradiation, for in large manufacturing establishments there are X-ray departments for diagnosis as extensive and as much used as the average hospital department. Here the problem may include protection of workers in neighbouring rooms, for unless walls and floors are very thick or are rendered impermeable by the use of lead, X-rays may pass through them and cause injury.

SYMPTOMATIC.—X-ray carcinoma should be treated either by diathermic coagulation under local anæsthesia, or by radium. Slight degrees of anæmia

recover on removal from exposure. In more severe degrees iron must be used, and when this fails blood transfusion is necessary.

INJURIES FROM RADIO-ACTIVE SUBSTANCES

Ætiology.—The gamma rays of radium appear to have a greater tendency than X-rays to cause aplastic anæmia; this impression is supported by the experimental evidence that the penetrative gamma rays of radium reach the bone marrow more readily than do X-rays. Three fatal cases of aplastic anæmia were reported in the London Radium Institute in 1920, one in a nurse and two in laboratory assistants. In 1925 the death of a chemical engineer working with radium and thorium-X was recorded.

The chief use of radium salts in industry has been in the manufacture of luminous paint for the figures of clocks and watches, and certain important parts of the machinery of aeroplanes. At two factories, one in New Jersey and the other in Connecticut, 38 deaths occurred among factory girls, chemists and physicists. The paint used contained insoluble radium sulphate, mesothorium and radiothorium. The girls affected introduced the paint into their mouths through the habit of pointing the brush between their lips and swallowed it for periods of from 1 to 4 or more years. The insoluble radio-active materials became deposited in the body to such an extent that even during life radio-active emanations could be detected in the expired air.

After death bone was found to be the tissue in which the materials had mainly accumulated. The anæmia resulted from the continuous bombardment of the hæmatogenous marrow by alpha particles, and it was found that these changes were quite different from those due to external irradiation with beta and gamma rays only. Radio-activity in the bones and teeth was demonstrated by autophotography. The bones when placed directly on photographic plates produced impressions in as short a period as 3 days. The total amount of radio-active material necessary to produce fatal results is extremely small. It is sufficient for 0·01 mg. to be distributed over the whole skeleton to produce a terrible death years after it has been ingested. Radium is thus the most deadly poison known; tetanus toxin previously held the record with a lethal dose of 0·22 mg.

Symptoms.—Dermatitis due to radium, isolated by the Curies in 1898, was reported in October 1900. Insufficiently protected tubes of radium salts kept in the waistcoat pocket for 6 hours produced reddening of the skin and within 10 days or so ulceration. Dermatitis has been reported in a number of persons engaged in making radium preparations, and less often in medical men. The ill-effects of ingestion of radio-active substances include severe anæmia, sometimes aplastic, necrosis of the jaw, spontaneous fractures and sarcoma of bone. The changes in the blood have been referred to as *anæmia radiotoxica*. The red cell count may drop below one million and the hæmoglobin below 20 per cent. Leucopenia, granulopenia and thrombopenia all occur. Purpura is followed by more serious bleeding, such as menorrhagia, hæmoptysis, hæmaturia and retinal hæmorrhages. Necrosis of the jaw occurs. It is similar to that produced by phosphorus, and is attributed to infection supervening upon changes in the bone. In certain cases necrosis of the jaw does not occur, but after a number of years generalised

changes in the bones develop with deformity and sometimes spontaneous fracture, a condition known as *radiation osteitis*. Bone sarcoma occurs in 25 per cent. of the cases of occupational mesothorium and radium poisoning.

Treatment.—Though medical practice is now almost safe so far as X-irradiation is concerned, matters are very different in the case of radium. There is no doubt that many people are affected by handling radium, chiefly by the gamma rays. Their penetrative powers are so great that it is not practicable to secure complete protection. In the case of persons who carry radium about the weight of lead they can bear to carry only partly protects them. Surgeons handling radium are also ill-protected. In the case of a man using 120 mg. of radium in the treatment of carcinoma of the cervix uteri, protection is very difficult as each time he has to handle the substance closely and carefully. It is obvious that ingestion or inhalation of radio-active materials in industry is highly dangerous, and that all occupations involving the handling of such substances should be strictly controlled and supervised. In the watch industry, outside New Jersey and Connecticut, the practice of pointing the brush with the lips is unknown, and no ill effects have been observed in other countries.

DONALD HUNTER.

ALCOHOLISM

Alcoholism is dealt with in this section mainly from the point of view of the physical effects. The subject may be conveniently divided into (1) acute alcoholism; (2) alcoholic coma; (3) dipsomania; and (4) chronic alcoholism. The section of Psychological Medicine (pp. 1836–1840) should also be consulted.

1. ACUTE ALCOHOLISM

Synonyms.—Acute Alcoholic Poisoning; Drunkenness.

Definition.—A person is said to suffer from acute alcoholism when as a result of alcohol he is unable to do with safety to himself or others that which he attempts.

Ætiology.—The effect of alcohol varies in different individuals, and depends not only on the amount taken but also on the physical state and mental stability of the patient.

Pathology.—Repeated sublethal doses cause no pathological changes in experimental animals. However, alcohol enhances the effects of other poisons and accelerates such degenerative processes as atheroma. Clinical observations on healthy human adults support these findings. It is a matter of common experience that post-alcoholic intestinal symptoms, malaise and headache, are more apt to occur when some other poison is taken at the same time. Examples are tobacco and the harsh acids of badly prepared wines. In alcoholic intoxication, the blood and urine alcohol reach a level between 0·1 and 0·3 per cent. The basal metabolism is raised, and there is great water loss from over-breathing, sweating, diuresis and sometimes vomiting. Alcohol depresses nervous activity. Reaction time is prolonged and perception dulled. The special senses become less acute, weakness of

accommodation and of ocular synergia occur with blurred vision and diplopia. The normal social inhibitions become dulled so that the animal tendencies escape repression, with consequent non-social or even anti-social behaviour. Indeed this lessening of inhibition is the end aimed at in taking alcohol, and allows a certain freedom and exhilaration in over-repressed persons. This escape from inhibition should not be regarded as an increase in general efficiency. In unstable persons, pathological mental tendencies may become uncovered, with resulting epileptic attacks either in the form of fits, or as "epileptic equivalents" such as mania a potu or automatism (see p. 1837).

Symptoms.—The clinical picture of drunkenness is well known. After sleeping the patient wakens with headache and the usual symptoms of a mild gastro-intestinal upset. As has been inferred before, there is little after-effect in the healthy person who drinks sensibly. People who have drunk unwisely or have taken too much tobacco will feel ill all the next day. They show the clinical picture of a mild melancholia with gloomy thoughts, poor volition and excessive irritability. Strong sensory stimuli are poorly tolerated. Mental concentration is poor, and there is marked lessening of general efficiency.

Diagnosis.—It is often impossible for an exact diagnosis to be made until the patient has been kept under observation, and this precaution should be taken where there is any doubt. No exact percentage of alcohol in the blood and urine can be fixed as the precise limit between sobriety and drunkenness for medico-legal purposes.

Prognosis.—Recovery usually takes place within 24 hours and can be hastened by appropriate treatment.

Treatment.—If the drunken person is seen before going to sleep, he should be given an emetic of warm sodium bicarbonate solution (60 grains to a pint) and subsequently encouraged to take a drink of water. The aim of this treatment is to remove any of the poison that remains in the stomach, to soothe the mucosa and to combat the dehydration. If the patient needs treatment and refuses it, apomorphine gr. $\frac{1}{20}$ or gr. $\frac{1}{10}$ hypodermically will induce vomiting within a few seconds and leave the patient amenable to subsequent treatment. He should then be put in a warm bed and allowed to sleep as long as possible. On waking a Seidlitz powder should be given and the patient encouraged to take plenty of fluid. This is usually acceptable in the form of tea. If tolerated, dextrose in some form should be given. When anorexia is marked, food should not be forced. If a great deal of alcohol has been taken, two grains of calomel can be given half an hour before the Seidlitz powder. If the patient has to get on with his work, 10 grains of calcium aspirin will improve his general feelings and combat the headache. Large doses of ordinary aspirin often irritate the stomach and should be avoided, as most of the symptoms of the next day are due to the gastro-intestinal upset. To give bitter alcoholic drinks as part of treatment is contrary to all medical principles and has no real therapeutic effect.

2. Alcoholic Coma

Synonyms.—Acute Alcoholic Poisoning; Wet Brain.

Ætiology.—Individual susceptibility varies so much and case histories are so falsified by prejudice and folklore that there are no reliable figures

of what constitutes a dangerous dose. Alcohol is much more dangerous in states of debility, whether such debility be the result of disease, exhaustion or hunger. Naturally beverages of high alcoholic content are more poisonous than those of low.

Pathology.—At post-mortem alcohol is present in all the body fluids. There is mucous catarrh of the stomach and evidence of right heart failure. The nervous system shows a moderate excess of cerebrospinal fluid and the superficial parts of the cortex are œdematous.

Symptoms.—These come on quickly. The euphoric exhilarated period is short, the patient becomes sleepy and soon passes into coma with stertor. Vomiting or even convulsions may occur during the early drowsy period, but neither of these symptoms is constant. In the coma, the patient lies in any position in which he is put, and is commonly found lying on his back. He is pale, collapsed and sweats profusely. In the early and middle stages he can be roused sufficiently to make a few disjointed remarks, and this has some diagnostic value. In these stages the pupils are dilated, the pulse full, the temperature subnormal, and the respirations deep. In the later stage the coma becomes dangerously deep, the pupils contract, the pulse weakens and the respirations are shallow. At all stages the limbs are flaccid, with diminished reflexes. In the early stages the plantar reflex is flexor, while in the later stages it cannot be elicited. Examination of the blood and urine show an alcohol content of 0·3 to 0·6 per cent.

Diagnosis.—It is of paramount importance to exclude cerebral trauma before making a final diagnosis of alcoholic coma. Sometimes the history of trauma is deliberately withheld by the person who has called the doctor. When there is a history of unconsciousness followed by a lucid interval and subsequent coma, this is good presumptive evidence of ruptured middle meningeal artery. The absence of such a history does not exclude this accident, as often the patient has taken alcohol, which implements the original concussion and does not allow the intermediate return of consciousness. Alcohol can precipitate other comas, notably diabetic coma, uræmic coma and epileptic coma. The urine must be examined in all cases, and when there is any doubt a lumbar puncture should be done. A careful general examination will reveal evidence of such conditions as renal disease or arterial degeneration, and may show scars on the tongue or elsewhere suggestive of epilepsy. Cerebral hæmorrhage or thrombosis must not be forgotten. Reference should be made to p. 1604 and elsewhere.

Prognosis.—With adequate treatment that is not too long delayed, this is good provided that the patient is otherwise healthy. The prognosis is unfavourable in those with cardiovascular disease, or when the acute attack occurs in the course of chronic alcoholism. Miosis is an unfavourable sign.

Treatment.—Treatment is necessary to combat shock and dehydration. Warm the patient, raise the limbs, and give fluids. The stomach should be washed out with one quart of a warm aqueous solution of sodium bicarbonate (60 grains to a pint), and a rectal drip of warm water should be started immediately. If there be evidence of heart failure with gross venous congestion, venesection should be done provided that the measures to combat shock and dehydration have been applied.

3. Dipsomania

Definition.—An intermittent compulsion to get drunk.

Pathology.—This is a compulsion neurosis.

Symptoms.—The periodicity varies in different individuals and in the same individual under differing stresses. Commonly it is about once a month. An irresistible desire to take large quantities of alcohol seizes the patient. Usually he begins drinking after work one day, takes a large amount, comes home with a bottle of spirits, and after drinking this becomes stuporose and has to be put to bed. The bouts tend to become more frequent. Usually no alcohol is taken between the attacks.

Prognosis.—A good deal of amelioration can be expected in expert hands; otherwise the outlook is not good.

Treatment.—The patient must be referred to a competent psychiatrist.

4. Chronic Alcoholism

Definition.—A patient is said to be a chronic alcoholic when he cannot carry on his ordinary life without alcohol.

Pathology.—This is primarily a mental disorder. The psycho-pathology is dealt with in the section on Psychological Medicine (pp. 1836–1840). Physically alcohol enhances degenerative tendencies, such as atheroma, and implements the toxicity of poisons; these effects are well seen in experimental animals. Gastro-intestinal catarrh occurs and results in deficient absorption of essential food elements. This is made worse because the patient prefers drinking to eating. In advanced cases achlorhydria is found. Bronchial catarrh and conjunctivitis are common, probably as a result of vitamin-A deficiency. Deficiency of vitamin B results in parenchymatous degeneration of nerves, and wasting of brain cells with chromatolysis. Ultimately the brain may be so wasted that the post-mortem appearance simulates that of G.P.I. Pachymeningitis hæmorrhagica is sometimes observed. The well-known susceptibility to pulmonary tuberculosis may be related to dietary deficiency. In the cardiovascular system atheroma and related degenerations are accelerated. However, it is a commonplace of pathology how little cardiovascular change there may be in an alcoholic subject. Gout is made much worse by alcohol, and osteoarthritis is common in alcoholics. The majority of persons with cirrhosis of the liver are heavy drinkers. No doubt some factor in addition to the alcohol is necessary to produce this condition, for it may be absent even in the worst chronic alcoholic. Alcohol is dangerous in diabetes, for it interferes with treatment and increases the tendency to complications.

Symptoms.—Typically the chronic alcoholic is a plethoric person with a plum-coloured complexion. The colour is most marked on the cheeks and nose. Its blue component is due to dilated small veins. After exposure to cold, the colour may darken to a deep mauve. The lips tremble, and there is a fairly coarse tremor of the hands. This tremor may affect the handwriting. The patient is fidgety, often wiping his mouth with his hand, fiddling with his tie, pulling at his ear or playing with his watch chain. He is restless in his chair, and often has tics involving the whole trunk or the head. He is often swift but superficial with his replies, and though his manner

is calculated to be disarming he is inclined to be irascible. He readily responds to the mood of the examiner. His eyes have an appearance that is variously described as glassy or watery. The conjunctivæ are red. His appetite is poor, and he has a preference for spicy and pungent foods. He rarely takes any breakfast, and does not feel himself until he has had a drink. On rising he clears his throat of much viscid mucus, which he usually refers to as "my catarrh." Often the hawking induces an attack of vomiting. Cases with much gastric catarrh vomit either on rising or at a fixed time afterwards. He is usually proud of the freedom of his bowels, but when careful inquiry is made it is found that he has diarrhœa. Night-rising once or twice is common. The majority of cases have attacks of paræsthesia in the limbs from time to time, and on examination the reflexes are found sluggish and the calves tender. In the presence of arterial degeneration a cerebral vascular accident may occur at any time, but more frequently the final illness is uræmia.

Neurological Complications.—Some degree of peripheral neuritis is common (see p. 1780). *Korsakoff's psychosis* may be present (see p. 1838). Sometimes in alcoholic neuritis the pupil is very sluggish to light. In such cases, if the neurological signs overshadow the mental, the condition is often referred to as *alcoholic pseudo-tabes*; if, on the other hand, the mental signs predominate over the physical, it may be called *alcoholic pseudo-paresis*. These terms are self-explanatory. *Acute hallucinosis* or the more serious *delirium tremens* are acute psychoses and are dealt with in the section of Psychological Medicine (see pp. 1837, 1838).

Prognosis.—(*a*) GENERAL.—As regards cure this is often bad. In many cases, however, suitable management leads to a good all round improvement. Intercurrent diseases, especially those of the respiratory system, are poorly tolerated. Pneumonia and tuberculosis have a much worse prognosis in these patients than in normal people. Anæsthetics are taken badly, and there is more likelihood of post-anæsthetic complications.

(*b*) NEUROLOGICAL.—This has been greatly altered for the better since the true nature of these complications has been understood, namely, that they are due to deficiency of vitamin B_1. Provided that no permanent damage has been done, cure can now be obtained of both the neuritis and the Korsakoff syndrome.

Treatment.—(*a*) OF THE CHRONIC ALCOHOLISM.—This is difficult, and usually disappointing in the hands of the general physician. The underlying causes are mental and these need the attention of experts. Should it be necessary to treat the patient in his own home without a psychiatrist the friends should be spoken to earnestly, and everyone in contact with the patient must be above suspicion because absolute withdrawal of alcohol is essential. Since the patient has been used to this nerve depressor, he may experience severe withdrawal symptoms and some simple sedative such as paraldehyde (min. 120) should be available. Where paraldehyde is not tolerated, soluble barbitone (medinal) (grs. viiss) is suitable. The patient's appetite will be poor, and may be encouraged by a simple stomachic before meals. After meals he should be given a sedative alkaline mixture, such as bism. carb. gr. 15, sodii bicarb. grs. 15, tr. bellad. min. 10, tr. card. co. min. 120, aq. menth. pip. ad min. 240. He should be handled sympathetically, and any outstanding domestic difficulties and worries resolved. Graduated doses

of strychnine are employed in many cases. Such treatment acts by suggestion. Better results will be obtained in these patients if at the beginning they are put to bed for a few weeks, and if the gastro-intestinal illness is treated intelligently. For psychological effect, the patient may be put on a rigid diet with all the quantities carefully prescribed and supervised. The form of the diet will depend on the circumstances, but it should be bland, well balanced, and rich in vitamins.

(*b*) NEUROLOGICAL.—Rest the affected parts, including the mind, and give large doses of vitamin B_1 (aneurine hydrochloride, thiamine hydrochloride). For the first two weeks, 6000 pigeon units (gr. 1/33 ; 1·8 mg.) should be given intramuscularly every alternate day, and thereafter, twice weekly. In addition, yeast extract (one drachm) should be given by mouth twice daily. After recovery the patient should continue to take vitamin B_1 indefinitely.

W. H. WILLCOX.
DONALD HUNTER.

LEAD POISONING

1. ACUTE LEAD POISONING

This is rare. It usually results from swallowing a large dose of a soluble lead compound, such as lead acetate, which is also known as sugar of lead, from its sweetish taste. It has occasionally occurred when white lead has been mistaken for chalk and when lead chromate has been used to colour cakes or confectionery.

Pathology.—There are the usual signs of acute gastro-enteritis, and the stomach may be covered with a whitish grey deposit. The wall of the stomach and duodenum is sometimes thickened and softened, and erosions may occur from the local action of the lead compound.

Symptoms.—An astringent metallic taste is at once experienced, followed by a feeling of constriction in the œsophagus. A burning sensation and pain are felt in the epigastrium, and vomiting occurs. The vomit contains opaque whitish material, due to the precipitated albuminate of lead and lead chloride, formed by the action of the lead salt on the gastric contents. Blood may also be present. Severe colicky pains occur in the abdomen, with rigidity of the abdominal muscles. Pressure on the abdomen gives relief, and the patient may bend forwards for this purpose, or lie on his abdomen. The tongue is coated, and the bowels are usually constipated ; but occasionally diarrhœa occurs. The stools are dark coloured, owing to the formation of lead sulphide. Prostration and collapse occur, if the abdominal symptoms are severe. There may be numbness or paræsthesia of the limbs, cramps in the legs, and partial suppression of urine. A blue line on the gums does not usually occur during the acute symptoms following a single dose of the poison.

The subacute form of poisoning follows the taking of repeated doses of a soluble lead compound. It may occur from repeated medicinal doses of lead acetate given to control diarrhœa. The symptoms of abdominal colic (lead colic) are pronounced, and the bowels are very constipated. The other symptoms of acute lead poisoning occur, but are less intense in character.

A blue line usually appears round the margin of the gums, owing to the formation of lead sulphide by the action of the decomposing food material around the teeth on the lead compounds in the gum tissue. If the teeth are frequently cleaned a blue line on the gums is less likely to be formed. If the symptoms are of long duration lead neuritis may result.

Diagnosis.—The diagnosis of acute or subacute lead poisoning can be confirmed by analysis of the vomit and fæces for lead during life, and after death by finding lead in the gastro-intestinal tract, liver, spleen and kidneys. Acute and subacute lead poisoning are rarely fatal.

Treatment.—If the case is seen within 3 hours of swallowing the poison, the stomach should be washed out with water. Sodium sulphate or magnesium sulphate in half-ounce doses, dissolved in half a tumblerful of warm water, should be given every 4 hours, until free purgation results, and this may be assisted by enemata, if necessary. The abdominal pain may be relieved by hot applications, repeated drinks of milk and large doses of calcium lactate, five grammes (75 grains) three times a day. In severe colic by the slow intravenous injection of 15 c.c. of a 20 per cent. solution of calcium gluconate, or of 10 c.c. of a 5 per cent. solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. If necessary this treatment may be repeated in 2 hours. Should it not be available a hypodermic injection of gr. $\frac{1}{60}$ atropine sulphate and gr. $\frac{1}{4}$ morphine sulphate may be given. For some weeks saline aperients and a high calcium diet should be given. The diet should contain 3 pints of milk daily, including milk puddings, junket and ice cream, together with butter, cheese and eggs.

2. Chronic Lead Poisoning

Synonyms.—Plumbism; Saturnism.

Ætiology.—Apart from a few cases arising from accidental causes, chronic lead poisoning is of occupational origin. Lead is now encountered in more than 200 industries. In Great Britain there are more than 1500 workers in the lead industries and 150,000 painters. It has been known clinically for more than a hundred years that absorption of lead through the respiratory tract is very much more important than by the gastro-intestinal tract, and this view has since been amply confirmed by experiments on cats. In the prevention of dust and fumes great success has been secured from the application of preventive measures by the Factory Department of the Home Office. Idiosyncrasy is a factor in the development of lead poisoning, certain persons being more susceptible than others. Alcoholism also seems to be a predisposing cause. The sources from which lead is derived in chronic poisoning are very numerous, and they may be divided into 3 groups.

1. *Occupational risks.*—Men are exposed to danger in the smelting and tinning of metals, in vitreous enamelling, pottery glazing, shipbuilding, coach painting, plumbing and soldering, house painting, and in the manufacture of white lead, red lead, litharge, rubber, glass, cement, varnish, coloured pigments, linoleum and electric accumulators. Lead smelters are exposed to the fumes and dusts of furnaces and flues. Lead burners and chemical plumbers use oxy-acetylene, oxy-hydrogen, or oxy-coal-gas blowpipes in their work. The very high temperature of such flames constitutes

a much greater risk than that faced by the domestic plumber who uses a spirit blowlamp. Painters are exposed when they rub down interior surfaces which have been painted with lead paint. The use of a blowpipe for burning off old paint is not without risk. A painter nowadays is very rarely exposed in mixing paint from the dry material, because it comes to him already mixed in oil. There is some risk to compositors who handle type metal, and to gasfitters who use red and white lead. It frequently happens that changes in methods or the appearance of new industries provide new causes of lead poisoning. This was the case with ship-breaking following on the scrapping of warships after the War of 1914–1918. In this industry the volatilisation of lead from the paint and red lead stopping on the armour plating occurs in the heat of the oxy-acetylene blowpipe flames used for cutting purposes. The great increase in the use of wireless receiving apparatus and motor cars has led to a greater number of cases of lead poisoning in electric accumulator factories. Sometimes the converse is true, and lead poisoning is found to show a remarkable diminution in a given industry. Thus, the substitution of machine methods for hand labour has abolished the disease among file cutters. The recent fall in the incidence of poisoning in coach painting is largely due to the enormous development of spray painting of motor cars with leadless cellulose paints.

2. *Accidental causes.*—Drinking water, especially if it is soft, or contains traces of acid derived from peat or dead leaves, may dissolve lead from lead pipes or cisterns and so give rise to poisoning. Beer or cider drawn from casks through lead pipes may become heavily contaminated. Aerated waters delivered from syphons with pewter or lead valves may give rise to poisoning. The lead glaze on earthenware vessels may be dissolved by vinegar, lemon juice, cider or home-made wine. The cooking of food in vessels tinned with solder containing lead may cause lead poisoning, especially if vegetable acids are present. Tinned foods sometimes contain lead from solution of the solder used in the tinning process. The lead foil used for wrapping sweets or food may contaminate them. Cosmetics, hair-dyes, and snuff weighted with litharge all have given rise to cases. Children with perverted appetites may chew the paint off their cots or toys. In Queensland, Australia, where the dry climate leads to flaking of painted surfaces, children have been poisoned owing to the habit of licking the raindrops off the painted balconies and roofs after rain has fallen.

3. *Abortifacient uses of lead.*—Lead attacks the chorion epithelium, causing abortion in pregnant women. A like effect has been observed in animals in the proximity of lead works. Lead oleate plaster, known as diachylon, has been used in certain districts by pregnant women in order to cause miscarriage, the substance being swallowed in small portions rolled up in the form of a pill. To do this is very dangerous, for if miscarriage comes about death occurs later from lead poisoning. In consequence the sale of lead oleate has been restricted by placing it in Part I of the Poisons Schedule.

Pathology.—In chronic poisoning lead is stored in the skeleton, and under certain circumstances is released to attack (i) muscle, causing abdominal colic and lead palsy; (ii) the reticulated red cell, causing punctate basophilia (stippling) and anæmia; (iii) the chorion epithelium, causing abortion; and (iv) the brain, causing encephalopathy.

A good deal is known about the physico-chemical behaviour of lead in the animal body. It is probably transported in the blood plasma as the insoluble tertiary phosphate in the highly dispersed or colloidal form. At different stages of intoxication its distribution within the body varies somewhat. When absorption is slow it migrates to the skeleton, where about 95 per cent. is held without harm during the chronic stage of plumbism. If, however, large quantities of lead are being absorbed or are being liberated from the bones, lead is distributed throughout the tissues and the percentage in the bones is reduced. Under these conditions acute symptoms of poisoning occur. It has been shown that the total amount of lead stored in the skeleton in lead workers varies from 0·2 to 0·8 gramme. This deposition of lead suggests a mechanism similar to that involved in the deposition of calcium phosphate. Repeated observations have shown that under conditions which favour storage of calcium in the body, the excretion of stored lead diminishes; and that when conditions are unfavourable for retention of calcium the excretion of stored lead increases.

In studies of lead excretion it is to be noted that normal individuals with no occupational exposure to lead may pass lead in the fæces and urine. The mean lead excretion of a group of Cincinnati medical students was found to be 0·24 mg. for each 24 hours in the fæces and 0·08 mg. in the urine. The figures quoted represent the average excretion calculated for each 24 hours, and as such they form an approximate guide only. In toxicological analysis no satisfactory figures can be obtained unless specimens of stool and urine are collected for at least 3 days. A man working in a dusty lead industry, in addition to inhaling lead, may swallow repeated small amounts and pass lead unabsorbed in the fæces. The only proof of absorption, therefore, is to find lead in the urine. If specimens be taken some weeks after removal from exposure, the output may reach about 1 mg. for each 24 hours in the fæces and about 0·3 mg. in the urine. It seems doubtful whether renal excretion ever much exceeds this figure under any circumstances. Under effective treatment, however, the fæcal excretion may rise to about 2 mg. in each 24 hours. It is necessary to emphasise that the presence of lead in the excreta is not necessarily proof that a lead worker is suffering from lead poisoning. Many such workers are insusceptible and have never suffered from any of the toxic episodes.

Lead palsy begins in the muscles, and fatigue determines the site of paralysis. The chemical explanation offered is that in regions of muscular activity the excess lactic acid which diffuses from the fatigued muscle cells combines with the lead phosphate in the blood to form lead lactate. As this soluble lactate comes into contact with inorganic phosphate at the surface of the muscle cells the lead is re-precipitated as insoluble phosphate causing alterations in the surface permeability.

Studies of the blood in lead poisoning show that the stippled red cell arises from the reticulocyte, and that the attack occurs peripherally and not in the marrow. Blood films can be prepared showing all stages between stippled fragments and typical reticulum. Stippled cells are never found in the bone marrow in lead poisoning. The presence of punctate basophilia in the blood is not, of course, a specific sign of lead poisoning. It is seen in pernicious anæmia, in leukæmia, in the anæmias of carcinomatosis and in pneumonia in infants. Its occurrence in these various conditions

is relatively rare and slight as compared with the frequency and intensity of its appearance during plumbism. For this reason the demonstration of stippling of the red cells in the blood has come to be considered as almost definite evidence of absorption of lead. It is not an absolute indication of the severity of lead poisoning, but it often runs parallel to the state of health. If on examination of the films its presence is detected in a sufficiently large number of fields of the microscope, further exposure to lead in the patient concerned should be prevented immediately. Punctate counts are of value in the prophylaxis of plumbism among lead workers and are essential in the adequate hygienic control of lead processes.

Except in cases of encephalopathy, which are now very rare, chronic lead poisoning is not a direct cause of death. In 1854 Garrod pointed out that gout was quite common among lead workers in Great Britain, but there is nothing to show that the occurrence of these two conditions in one patient was other than fortuitous. Chronic lead poisoning produces no characteristic post-mortem changes. It perhaps accelerates arterial degeneration (arteriosclerosis). Chronic nephritis with renal insufficiency is a common cause of death in lead workers. The accompanying hypertension frequently leads to cerebral hæmorrhage at a comparatively early age.

Clinical History.—The past occupations of the patient should be inquired into, for latent lead poisoning is well known to occur. The present occupation is obviously of great importance and the exact details of the work he does should be elicited from the patient himself. Often a man's occupation does not at first sight suggest that he is exposed to compounds of lead. A man describing himself as a fitter may be exposed to dust or fumes of lead; this fact is only elicited in answer to a leading question. The occupation of a cooper becomes dangerous when the barrels worked upon have contained compounds of lead. Vitreous enamellers working, for example, on baths, sift a powder containing lead silicate on to the bath which has been heated in a furnace. They sometimes use a compressed-air apparatus which forces the enamel through a sieve. In the electric accumulator trade pasters fill the spaces in accumulator plates with a paste containing litharge and red lead. Colour manufacturers grind colours into a fine powder under edge runners with the necessary production of much dust. Amongst other things they grind lead chromate and red lead. A slate mason may construct storage tanks by fixing together slabs of slate with materials containing oxides of lead. A bullion refiner may use a process in which he adds lead to refinable silver in a furnace and taps off molten litharge. A rubber compounder adds oxides of lead to crude rubber in preparation for vulcanisation. A girl describing herself as a perambulator maker may be employed painting the body work of perambulators and then rubbing down the surface with dry sand-paper. An embroidery worker sometimes stencils materials by dabbing on the pattern commercial white lead instead of chalk.

Symptoms.—Individual opinion differs widely as to what is necessary for the definite diagnosis of lead poisoning. The diagnosis of intoxication as distinguished from absorption should be based upon evidence as to the presence of one or more of the toxic episodes. These are colic, palsy, anæmia, and encephalopathy. Constipation and slight stippling of red cells are insufficient without one of the toxic episodes to establish a diagnosis of poisoning. The urine should be collected for at least 3 days and examined

for lead, but a positive result is not proof that the patient is suffering from lead poisoning for he may be insusceptible.

Lead colic.—This is the most common and dramatic of the acute manifestations of plumbism. It is probably ten times as common as lead palsy. An acute attack of colic is usually preceded by several days of constipation. The pain is of a tearing or griping nature and of variable intensity. It is usually situated around or below the umbilicus, and the patient often indicates where it is by spreading both hands widely over the lower abdomen. While suffering from colic the patient is cold, pale, and often drenched with perspiration. He commonly bends over and may writhe about the bed in intense pain. Examination shows a scaphoid abdomen, held tense, but not showing any true rigidity. Vomiting quite frequently occurs at the onset of the pain.

Lead palsy.—This does not belong to the category of polyneuritis, either clinically or pathologically. It is in the first instance a muscle disease. Fatigue plays a most important part in determining the sites attacked. Where the muscle palsy is neglected the lead attacks the motor nerve fibres and ultimately the anterior horn cells of the spinal cord. (See also p. 1789.) Paralysis does not appear to be closely related to length of exposure. It may develop during the first month of work, or only after many years' exposure. The commonest form is the well-known wrist-drop which begins usually in the right hand and later becomes bilateral. The palsy first appears in the long extensors of the middle and ring fingers. It spreads to the other fingers, and then to the long extensors of the wrists. The supinator longus, and usually the long abductor of the thumb escape. The brachial type of paralysis involves the deltoid, biceps and supinator longus, but it is very rare for this to occur without wrist-drop. A third form of lead palsy in which progressive atrophy occurs of the thenar and hypothenar eminences, together with the interossei, used to be common in the left hand of file-cutters. In view of the theory that fatigue plays an important part in determining the site of lead paralysis, this observation is of great interest, for in their work file-cutters not only used particularly the muscles mentioned but placed the greatest strain upon the left hand. The substitution of machine methods for hand labour has abolished lead poisoning amongst file makers. Lead palsy rarely occurs in the lower limbs, but when it does so it affects the extensors of the toes, giving rise to foot-drop.

The lead line.—The lead line consists of fine granules of pigment arranged in the form of a very dark blue stippled line within the tissues of the gum about a millimetre from the border of the teeth. It is more marked round infected or dirty teeth, and is occasionally found on the mucosa of the cheek opposite such teeth. In spite of the fact that the pigment lies actually within the tissues and cannot be rubbed off, careful cleaning of the mouth and teeth is often found quickly to eliminate the line. Its clinical significance should be clearly recognised. Its intensity and size provide a rough guide to the duration and severity of exposure to lead.

The anæmia.—Secondary anæmia with basophil punctation (stippling) of the red cells is characteristic. It is usually mild, and it is rare to find less than 3 million red cells per c.mm. Because of the loss of circulating red cells there is compensatory regeneration of erythrocytes with a hig reticulocyte count.

Encephalopathy.—Most of the ancient writers speak of the frequent occurrence of convulsions in lead poisoning, but fortunately with the improvement of industrial conditions the incidence of lead encephalopathy has progressively decreased until to-day cases are very rarely seen. It is the most dramatic manifestation of lead poisoning, and is always of serious prognostic significance. In severe cases of plumbism the patient is dull, with poor memory, and inability to concentrate. The onset of encephalopathy is nevertheless sudden, usually with epileptiform convulsions. It may be divided into three groups—convulsive, comatose and delirious. The lymphocyte count in the cerebrospinal fluid may reach 100 per c.mm.

Diagnosis.—There is always a danger of wrongly attributing to lead poisoning any symptoms which may occur in persons exposed to lead. Acute appendicitis, chronic gastric or duodenal ulcer, and carcinoma of the stomach occur from time to time in lead workers. They must be carefully differentiated from colic. Equally a lead worker can suffer from pernicious anæmia or secondary anæmia due to piles, melæna or hæmatemesis. It is important to remember that lead poisoning has to be very severe indeed before the red cell count drops below 3 million. In industrial cases confusion is unlikely to occur in regard to the blue line. A similar phenomenon is commonly seen in patients under treatment with bismuth preparations given intramuscularly. The differential diagnosis of lead palsy should give rise to no difficulty, especially as the changes are entirely motor. In a case of peripheral neuritis in which there are motor, sensory and pigmentary changes the possibility of arsenic poisoning must be considered. Litigation hysteria is all too common in the lead worker. The manifestations include hysterical spasm of the hand and arm, weakness of various movements, including the flexors of the wrists and fingers, glove and stocking anæsthesia, complete hemi-anæsthesia and hysterical aphonia. Such symptoms are rarely alleviated until legal proceedings are completed.

Treatment.—PROPHYLACTIC.—The treatment of chronic lead poisoning is essentially preventive. Food and drink containing organic acids should not be stored in earthenware vessels glazed with lead. Supplies of soft water for drinking purposes when delivered through lead pipes should be artificially hardened by the addition of calcium salts. Lead pipes used to convey beer or cider from the cellar to the bar engine in public houses must be lined with tin. Children's toys and cots must never be painted with lead paint. The law must restrict the sale of lead oleate and forbid the addition of litharge to snuff in order to make it heavy.

In industry less than 100 cases of lead poisoning were notified in 1938 as compared with more than 1250 in 1889. In Great Britain preventive measures are carried out with such success that the majority of cases of lead poisoning are mild. It is unusual to-day to meet with a case either of severe colic or of extensive palsy, and encephalopathy has been abolished. The most important single measure of prophylaxis is the prevention of dust and fumes. In achieving this, great success has been secured from the application of the principle upon which Sir Thomas Legge always laid so much stress, namely, to apply methods entirely external to the workman—methods over which he himself can exercise no control. One such method is exhaust ventilation applied through hoods at the point of origin of dust or fumes. Benches, tools, floors and walls must be spotless, often at the expense of

the constant vigilance of several good foremen. No scrap lead nor dry white lead should be handled unless it has been thoroughly soaked with water from a hose. As far as possible mechanical means, such as cranes, rails, hoists, covered conveyors and hoppers, and automatic packing machinery must be substituted for hand carriage.

Fortunately about 50 per cent. of the white lead manufactured in Great Britain is never handled in the dry state. It is made by the stack process and leaves the stack in a wet state to be converted into an aqueous paste, mixed with linseed oil, and made into an oily paste in automatic closed-in machines without dry grinding. Since a white-lead worker may handle in the course of a day at least as much white lead as a painter handles in a year, the value of this wet pulping method will at once be realised. In the manufacture of litharge and red lead it is impracticable to use wet methods, and it is therefore necessary to use machinery designed to minimise dust. Since 1927 it has been illegal for a painter to rub down by dry methods any indoor structure previously treated with lead paint. A satisfactory damp rubbing down process has been introduced in which waxed sand-paper is repeatedly dipped in the vessel of water.

In addition to cleanliness in the workplaces, personal cleanliness is of the first importance. Cloak-rooms, washing-rooms, mess-rooms, baths, nail-brushes, towels and soap must be provided. The hands should always be washed before eating and the work-people urged to take a warm bath frequently. The bringing of food or drinks into the work-rooms should be forbidden, and so also should smoking at work. Medical examination of the workers exposed must be carried out periodically. At present there is no biological test by which to select workmen immune to the toxic effects of lead. Since they have been found unduly susceptible, it is necessary to forbid the employment of pregnant women and of all persons under 18 years of age in the potteries and other lead trades.

In the prevention of lead poisoning a diet of high calcium content plays its part. In lead works in Great Britain it has for many years been customary to provide the workmen free of cost with a glass of milk each morning. This is empirical treatment of considerable merit, anticipating as it did by many years the discovery that a high calcium intake assists the storage of lead in a harmless form in the bones. Workers should, in addition, take aperients regularly. Any worker who develops one of the toxic effects of lead has thereby proved his susceptibility, and ideally he should never again work in any department of a lead works.

CURATIVE.—Repeated observation has shown that with a high calcium diet lead excretion tends to diminish rapidly. This provides a means for controlling the storage of lead in the organism. To store lead in the bones so that it will not be free in the circulation to cause damage, it is only necessary to give a diet containing much calcium in the form of milk or calcium lactate. This produces a positive calcium balance which favours the storage of lead as a harmless deposit in the bones. In cases of lead poisoning showing toxic symptoms the diet should contain 3 pints of milk daily, including milk puddings, junket and ice-cream, together with butter, cheese and eggs. In the presence of acute symptoms it is important not to attempt elimination of lead, because so much is already circulating that it is safer temporarily to favour further storage. The first step should

then be to prescribe large quantities of calcium lactate, 5 grammes (75 grains) three times a day. When the calcium intake is sufficient most of the lead is stored in the bones, and the patient presents no symptoms.

Lead colic.—It is necessary to use local applications of heat, pressure and moisture. The bowels should be moved as early as possible by means of enemas of olive oil and warm water, and by the internal administration of magnesium sulphate along with belladonna and carminatives. Treatment by a high calcium diet usually brings relief within 2 days. The relief of lead colic by calcium therapy involves more than the mere tendency of calcium to favour storage of lead. There is evidently an anti-spasmodic action on involuntary muscle as well. The pain of lead colic is probably due to a contraction of the tonic ring in the intestine with marked peristalsis approaching this. A high calcium diet and the use of large doses of calcium lactate usually brings relief. In severe cases, by the slow intravenous injection of 15 c.c. of a 20 per cent. solution of calcium gluconate, or of 10 c.c. of a 5 per cent. solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. The patient feels hot and flushed, and may vomit. The effect upon the pain is striking, and is superior to that of any other treatment. If necessary the injection may be repeated in 2 hours. Should such treatment not be available a hypodermic injection of $\frac{1}{60}$ grain atropine sulphate may be given.

Lead palsy.—During the development of lead palsy, a high calcium diet should be used to favour storage of lead. Massage, electrical treatment and strychnine are useful. In the early stages the hands, when affected by wrist-drop, should be supported on splints. The paralysed muscles may be stimulated by an induction coil, with or without a water bath, but overstimulation must be avoided since it induces fatigue, and so does harm.

Encephalopathy.—In Great Britain the Home Office regulations, by the control of dust and fumes, have abolished encephalopathy. In the few cases with which he has had to deal in the United States, Aub has had good results with a high calcium diet. Of six definite cases three occurred before the treatment was in use, and these all died. The other three were given large quantities of milk and calcium lactate and all promptly recovered.

Elimination of lead.—Experimental studies of the conditions favouring and hindering liberation of lead from the bones have contributed to the knowledge of the treatment of lead poisoning. In cats experimentally poisoned with lead, acute symptoms may develop during starvation and at necropsy lead is found distributed more generally through the body than is typical of the chronic condition. This suggests that during starvation acidosis sets lead free from the bones. The probable reason for this is the conversion of the tertiary phosphate of lead into the secondary phosphate which is exactly one hundred times more soluble. Hence the ingestion of acid as a method of treatment probably serves to liberate lead from the skeletal stores by converting it into a more soluble salt.

Acidosis may be produced by the use of phosphoric acid, but it is more satisfactory to give large doses of ammonium chloride. Chronic lead poisoning may be treated by the cautious administration of this substance in doses of 1 gramme (15 grains) given in a glass of water eight or ten times daily for 3 weeks at a time. Loss of appetite and headache signify the limit of tolerance to such treatment, and the dosage should be reduced if these

symptoms appear. In no case should ammonium chloride be used until a few weeks after the acute toxic episode has passed. A diet with a very low calcium content facilitates release of lead from the bones. In such a diet all milk, milk products, green vegetables and eggs are omitted. It may contain meat, liver, chicken, potato, peas, rice, tomato, banana, apple, lemon, tea, coffee, sugar, honey, salt and pepper. All bread must be prepared without milk. Butter fat must be substituted for butter. This is prepared by melting butter in hot water and skimming off the butter fat. In those places where the water supply is hard, vegetables should be cooked in distilled water and all drinks made up with it.

Various observations, particularly on animals, indicate that it is useless to attempt elimination of all the lead stored in the body. As this would doubtless require several years, it is probably desirable to eliminate only the most readily mobilised lead. In prolonged observations the results indicate that after a certain point elimination of lead becomes progressively more difficult. When this stage is reached it seems more practical to favour retention in the bones by maintenance of a positive calcium balance. Thus after 3 weeks' treatment by a low calcium diet and ammonium chloride, there should be a rest period of a week with normal diet and abundance of milk to correct the calcium deficiency. Treatment to accelerate elimination should then be re-instituted.

Potassium iodide has been employed by clinicians since 1844. It is not as effective as treatment by acidosis, but has the advantage of ease of administration. The dose should be increased from 5 grains three times a day to 15 grains three times a day. Its physiological effectiveness appears to diminish progressively after the first few days of treatment. Neither ammonium chloride nor potassium iodide should be used in the presence of nephritis or of toxic symptoms. Should any toxic episode appear during the use of ammonium chloride or potassium iodide, these drugs must be stopped and a high calcium diet at once used to favour the storage of lead. Occasionally cases of latent lead poisoning occur, that is to say, cases in which symptoms have been precipitated by various forms of treatment long after exposure to lead has ceased. Thus a lead line or wrist-drop may follow upon the use of potassium iodide as an expectorant.

It is necessary to emphasise the difference between the use of agents which assist excretion of lead and those assisting its storage. The acidosis method of lead elimination is so potent that its use during colic or any other toxic episode might prove fatal from the further mobilisation of lead at a time when the reverse procedure is essential. It is scarcely necessary to add that such treatment should never be used as an excuse for negligence in enforcing all the known measures for the prevention of exposure and absorption.

3. Tetra-ethyl Lead Poisoning

Tetra-ethyl lead is an organic lipoid-soluble compound, and is absorbed directly through the skin. It is added to petrol as an anti-knock substance in the proportion of 1 in 1400. In 1923, when it was first manufactured in the United States, 149 cases of encephalopathy occurred in men employed on the plant. Within 17 months 11 men died and 1 became insane. Much excitement and alarm was caused, and this led at first to the prohibition of

the manufacture. The men affected suffered from restlessness, talkativeness, ataxia, insomnia and delusions. There were no paralysis nor convulsions, but the condition terminated with violent mania, the patient shouting, leaping from bed, smashing furniture and acting as if in delirium tremens. By meticulous attention to detail it is possible to manufacture tetra-ethyl lead and to blend it with petrol without risk to the worker. Even so, ethyl petrol should not be used for cleansing the skin and to prevent this it is marked by a dye. There is no need for apprehension as to the possibility of the poisoning of garage workers by lead from the exhaust gases of motor cars.

DONALD HUNTER.

ARSENICAL POISONING

Arsenic is the most important of the irritant poisons, and owing to the almost tasteless property of many of its compounds and preparations it is perhaps the commonest poison used for homicidal purposes. At one time it had a reputation as a cosmetic, and was added to face powders and skin lotions. It is practically never used now for such purposes.

Occurrence.—White arsenic, i.e. arsenious acid, or arsenious anhydride, As_4O_6, is the most important of the compounds of arsenic. It occurs in the form of a white powder, or in lumps like glass or porcelain (vitreous arsenic). The powdered form resembles powdered sugar or flour, and when mixed with solid food is tasteless. It is slightly soluble in cold water, an ounce of cold water dissolving from a half to one grain. In boiling water it is twelve times more soluble, from 6 to 12 grains dissolving in an ounce. Alkaline solutions readily dissolve arsenic. If white arsenic is sold to the public the law requires that it should be mixed with soot or indigo to colour it. It is used in the composition of sheep dip, arsenical soap and rat poison.

Metallic arsenic is a black powder. It is very poisonous, and is used for killing flies. *Copper arsenite* (Scheele's green) is bright green in colour, and used to be employed for colouring wall-paper, toys, floorcloths and fabrics. Its use for such purposes has fortunately been abolished. *Arsenious sulphide*, or orpiment, is a yellow powder known as king's yellow. *Arsenic acid*, in the form of its potassium and sodium salts, which are white, crystalline and soluble in water, is used as a fly poison and in the manufacture of aniline dyes. Injurious effects, such as local skin eruptions, are sometimes caused by the action of the arsenical compound present in the dye of stockings. *Sodium arsenite*, in the form of solutions of arsenic in caustic soda, or in sodium carbonate, is commonly used for the preparation of fly-papers, weed-killer, preservative for wood and arsenical sprays for fruit trees. Weed-killer and some of the so-called preservatives for wood contain from 20 to 40 per cent. of arsenic in solution, and are intensely poisonous. Both weed-killer and the arsenic obtained from fly-papers have been used for homicidal purposes.

Arsenic in food.—Accidental contamination of food with arsenic, or its preparations, such as weed-killer, has occurred. Arsenical pigments have been used for colouring sweets and cakes, with fatal result. A serious outbreak occurred in 1900, owing to the contamination of commercial glucose by

arsenic. Sulphuric acid prepared from pyrites and containing a considerable amount of arsenic had been used in the process of the conversion of starch into commercial glucose, so that the latter became impregnated with arsenic. The use of the glucose in the manufacture of beer led to the outbreak of arsenical beer poisoning which occurred in Manchester and the North of England. A Royal Commission investigated the cause of this epidemic, and safeguarded the further occurrence of such poisoning. Limits of the amount of arsenic permitted in food-stuffs were fixed at $\frac{1}{100}$ gr. per gallon for liquids and per pound for solids.

Arseniuretted hydrogen, or arsine, is a very poisonous gas. It is produced when hydrogen is generated in the presence of a compound of arsenic, for example, in the action of mineral acids on impure metals, as occurs in metal pickling and in balloon filling.

Dimethylarsine is a poisonous gas produced by the action of moulds upon certain compounds of arsenic.

The *arsenobenzene* derivatives which are extensively used in the treatment of syphilis and other diseases, may give rise to fatal poisoning.

The varieties of arsenical poisoning are—(1) acute, (2) chronic, (3) arseniuretted hydrogen poisoning, (4) dimethylarsine poisoning, and (5) poisoning by arsenobenzene derivatives.

1. Acute Arsenical Poisoning

Pathology.—The stomach contents usually contain much mucus, which may be blood-stained. The signs of gastro-intestinal inflammation are present. The mucous membrane is swollen, red and congested, and petechiæ are usually well marked. The redness is most marked on the summits of the rugæ. When the arsenic has been taken in solid form, white or pigmented particles may be seen on the mucous membrane of the stomach. The duodenum is red and congested, and petechiæ may be present; there is usually marked yellow staining, due to altered bile. The small intestine may show similar signs to the duodenum, but these diminish on passing downwards. The liver, kidney and other organs may show cloudy swelling. In fatal cases the arsenic absorbed into the tissues has a preservative action, and tends to delay putrefaction.

Symptoms.—When the poison is taken by the mouth, if diluted well or mixed with food, no taste or pain in the mouth or throat is experienced. The symptoms begin within an hour if the stomach is empty; but may be delayed if the stomach is full, and if the poison is in the solid state there will be further delay. A burning pain occurs in the epigastric region, and nausea and vomiting usually follow. The vomit will contain any food present in the stomach, and there is often much mucus. Bile is usually present, and sometimes streaks of blood. As the poison is passed on to the intestine, abdominal pain, of a griping or colicky type, and usually diarrhœa occur. The stools are watery, and may contain flakes of mucus. The continued vomiting and diarrhœa cause exhaustion, faintness and collapse. Cramps in the legs may occur, but are not a constant symptom. In a severe case restlessness, stupor and coma develop, and death follows shortly. Death in an acute case may occur within 24 hours, or may be delayed for 3 days or more. When several repeated doses are taken, so that the symptoms are protracted over

several days, some of the symptoms of chronic arsenical poisoning may develop.

Fatal dose.—Two grains of arsenic have caused death in a woman, and this is accepted as a possible fatal dose.

Treatment.—The stomach should be washed out, and afterwards as an antidote freshly precipitated ferric hydroxide may be given. This is prepared by adding to half a tumblerful of water half an ounce of tincture of perchloride of iron and also sodium carbonate solution till the mixture is distinctly alkaline. Pain is relieved by the hypodermic injection of morphine. Demulcent drinks should be given, and the usual stimulant treatment for collapse.

2. Chronic Arsenical Poisoning

Symptoms.—The gastro-intestinal symptoms—nausea, abdominal pain, vomiting and diarrhœa—are not prominent, and even may be absent. The tongue is often covered with a silvery white fur. General malaise, anorexia and anæmia are usually present. Irritation of the throat and huskiness of the voice, due to the presence of pharyngitis and laryngitis, result. Conjunctivitis may occur, with redness and swelling of the eyelids. Skin affections, such as erythema, herpes, pigmentation, or erythromelalgia, are commonly to be noted.

If taken medicinally, or otherwise, over a long period, arsenic produces a finely mottled general brownish pigmentation of the skin. It affects principally the covered parts. The mucous membranes are not involved. Thickening of the epidermis of the soles and palms, and irregular thickening of the nails are present in long-standing cases. In some cases salivation is a marked feature, paroxysmal attacks of excessive secretion of saliva occurring. Symptoms of multiple neuritis are likely to develop, and these affect both the upper and lower extremities.

Long-continued poisoning causes anæmia, peripheral neuritis, progressive wasting and weakness, death resulting from exhaustion and cardiac failure, ascites and general œdema occurring towards the end. The urine, fæces, the distal portions of the hair and the nails contain arsenic, its detection serving to confirm the diagnosis during life. The tests for arsenic will be found in works on toxicology. It must be remembered that in cases of suspected arsenical poisoning the diagnosis can always be made with certainty by an analysis of the urine, vomit and fæces, and these should always be taken for examination, the tests being made by an expert toxicologist.

It is important to remember that acute arsenical poisoning, where a large dose is taken, may (if the patient recovers from the acute attack) be followed by symptoms of chronic arsenical poisoning. Severe peripheral neuritis may follow acute poisoning from a single dose of arsenic.

Treatment.—This consists in the prevention of the absorption of arsenic in any way, and eliminative and stimulant treatment.

3. Arseniuretted Hydrogen Poisoning

Ætiology.—Arseniuretted hydrogen is a poisonous gas which is not manufactured in industry but is evolved as an accidental by-product in

certain processes. The majority of cases have been due to the use of acids and metals contaminated with arsenic. The occupations concerned are the extraction of mineral ores, pickling and galvanising of metals, cleaning of acid tanks, the manufacture of hydrogen and its use in ballooning and the making and charging of accumulators. Poisoning may arise from the action of water upon metallic arsenides. Cases have also occurred when ferro-silicon, a substance used for hardening steel, has come in contact with water, when a mixture of arseniuretted and phosphoretted hydrogen is evolved.

Pathology.—The gas is inhaled and acts at once by hæmolysing the red cells within the vessels. Hæmolytic jaundice and anæmia follow. Death may occur from anuria if the renal tubules become blocked with hæmoglobin. Degenerative changes in the cells of the liver and kidneys, and numerous petechiæ on the mucous and serous membranes, are to be noted.

Symptoms.—Malaise, headache, dizziness, shivering and hæmoglobinuria occur within a few hours. Within 24 hours there is nausea, vomiting, and jaundice, and by the third day anæmia in which the red cell count may fall below 1,000,000 per c.mm. Delirium, stupor and coma precede death.

Diagnosis.—Mild cases are often mistaken for food poisoning. The sudden onset of hæmoglobinuria and jaundice at once suggests inquiry into a man's occupation.

Prognosis.—Mild cases quickly recover. The mortality rate is 30 per cent.

Treatment.—Workshops should be adequately ventilated and processes known to be risky should be forbidden in confined spaces. Sometimes a breathing apparatus suitable for use in irrespirable atmospheres must be employed. Such an apparatus consists of an oro-nasal mask with tube connection to the outer atmosphere. The wearer draws fresh air through the tube by his inspiratory efforts and expels the expired air through a valve in the mask.

4. Dimethylarsine Poisoning

The use of Scheele's green (cupric arsenite) in the preparation of artificial flowers and wall-papers has now only historical interest, because aniline colours have almost entirely taken the place of arsenic in these processes. The mould *Penicillium brevicaule* growing in the paste behind wall-papers in damp rooms liberated dimethylarsine. The same process may occur in damp houses where coke breeze containing arsenic forms a constituent of the plaster on the walls. The use of concrete blocks containing this substance and the deliberate addition of arsenious oxide to cements to increase their rates of hardening are clearly undesirable. The symptoms of poisoning are coryza, conjunctivitis, gastro-enteritis and tinglings in the extremities. Some cases are fatal.

5. Poisoning by Arsenobenzene Derivatives

Arsenobenzene derivatives, such as arsphenamine, neoarsphenamine, and sulpharsphenamine, are usually administered intravenously. After a full dose (0·6 g. arsphenamine, 0·9 g. neoarsphenamine) nausea, a slight rise of temperature, with perhaps vomiting and a little diarrhœa, may occur in the following 24 hours, after which the patient is quite well. Occasionally

severe vomiting and diarrhœa, with furred tongue, erythematous rash and acute gastro-intestinal symptoms, may follow. In such cases it is probable that there has been some decomposition in the solution administered, the symptoms resembling those of acute arsenical poisoning. This type of poisoning is rare. Arsphenamine and allied compounds, especially after the administration of successive doses, sometimes cause such damage to the liver that extensive necrosis occurs and toxic jaundice develops, which may be fatal.

When dangerous toxic symptoms occur after arsphenamine, they are usually of the following type: After an interval of 2 or 3 days, vomiting and restlessness, delirium, stupor, often with twitchings of muscles, convulsions and Cheyne-Stokes breathing, occur. Sometimes jaundice is observed. Coma develops, with suppression or urine, and death may occur within 48 hours. The symptoms are the result of impairment of the function of the liver and kidneys. The prognosis is very grave.

Treatment consists in the administration of alkalis by the mouth and bowel, and saline per rectum. Glucose, milk and fruit juices should be given freely.

In order to protect the liver, dextrose and calcium lactate may be given a few hours before administering arsphenamine compounds. It should also be borne in mind that if full doses are employed, a fortnight is required for the excretion of the drug, and that interval should elapse between the doses. Where submaximal doses are used, *e.g.* 0·4 g. arsphenamine or 0·6 g. neoarsphenamine, weekly injections are often administered, but after a few doses an interval of 3 or 4 weeks should be allowed to avoid a cumulative effect.

See also Toxic Effects of Arsphenamine Remedies, p. 210.

MERCURIAL POISONING

(1) Acute Mercurial Poisoning

This usually arises from the absorption of mercuric chloride, also known as corrosive sublimate ($HgCl_2$), which is largely used in medicine as a disinfectant or antiseptic. Biniodide of mercury has similar uses. Both are usually purchased in the form of tablets ready for solution in a required amount of water. Acute poisoning generally occurs from the taking of the poison by the mouth, but it may also arise from the use of mercuric compounds in solution as uterine or vaginal douches. Calomel (mercurous chloride), even if taken in large doses, does not give rise to the same degree of acute poisoning, owing to its insolubility. The writer has met with 2 cases in which over 100 grs. of calomel were taken with suicidal intent, and beyond some vomiting and diarrhœa, little harm resulted.

Symptoms.—If mercuric chloride is swallowed in tablet form there is risk of local corrosion and perforation of the stomach, with rapidly fatal result.

When taken in solution, or in tablet form with water, or on a full stomach, an acrid metallic taste is experienced, followed by a sense of constriction in the throat. A hot burning sensation occurs in the mouth and œsophagus. Acute abdominal pain and vomiting take place. The vomit contains much

slimy mucus and often blood. Diarrhœa and tenesmus occur. Collapse is associated with these early symptoms. The mouth and pharynx may show signs of local damage, such as white swollen patches, which may be followed by sloughing. Unless the poison is quickly removed by gastric lavage the dangerous sequelæ of absorption rapidly follow.

The two chief dangers of acute mercurial poisoning are: (1) suppression of urine and uræmia, due to the toxic action of the poison on the renal epithelium causing cloudy swelling, necrosis and loss of function; and (2) ulcerative colitis, the result of the action of the poison on the mucous membrane of the colon, whereby extensive necrosis and sloughing occur. Suppression of urine follows the absorption of the poison, and urine secretion may almost entirely cease. The cessation of renal secretion is followed by a rapid rise in the blood urea, and after 4 or 5 days dangerous symptoms of uræmia, vomiting, stupor, delirium, coma and convulsions set in, which are generally rapidly fatal. The ulcerative colitis begins about 24 hours after the intake of the poison, and is associated with profuse diarrhœa, and the passage of sloughs and shreds of necrotic mucous membrane and blood. The colitis may be caused as the result of absorption of the poison into the blood stream apart from its direct local action on the colon. Death may occur from exhaustion, and absorption of toxic products from the raw surface of the bowel.

Acute mercurial poisoning is always accompanied by a very severe stomatitis, which begins within a few hours. The breath is foul, the mucous membrane becomes ulcerated, the teeth may become loose and necrosis of the alveolus occur.

Five grains of mercuric chloride is a fatal dose for an adult, unless the poison is removed by gastric lavage within an hour or two.

Treatment.—Immediate gastric lavage should be employed. Afterwards, white of egg and milk should be given freely. The collapse, suppression of urine, ulcerative colitis and stomatitis are other symptoms treated by the appropriate methods for such conditions.

(2) Chronic Mercurial Poisoning

Ætiology.—This condition occurs chiefly amongst workers in the metal, or amongst those who are constantly brought into contact with compounds of mercury; for example, those engaged in mining and separation of the metal, *e.g.* at Almaden in Spain, at Idria in Austria, and at the mines in California, China, Peru and the Ural Mountains. Mirror makers, thermometer and barometer makers, and those engaged in the manufacture of chemical and electrical apparatus in which metallic mercury is used, are exposed to risk. Those engaged in the frequent handling or grinding of mercury compounds are sometimes attacked. It must be remembered that mercury is volatile at ordinary temperatures, and those working in ill-ventilated rooms where mercury is exposed are liable to attack. Cases have been recorded of chronic mercurial poisoning from the amalgam in tooth stoppings, and from sojourn in a respiration apparatus fitted with mercury air-valves. The nitrate of mercury is used in the felting of fur, and hatters' furriers are liable to chronic poisoning unless they are properly protected. The condition may result from the continued administration of calomel or blue pill, from

the inunction of mercury ointment, or from the prolonged use of mercurial vaginal douches.

Symptoms.—Dyspepsia, anæmia, general cachexia, with loss of weight and strength, occur. Sometimes a blue line is seen on the gums if the teeth are neglected. Stomatitis is one of the most constant symptoms; increased salivation and marked fetor of the breath occur, and are associated with tenderness of the gums and looseness of the teeth. Colitis, often of an ulcerative type, may result from chronic mercurial poisoning. It is a dangerous complication and difficult to treat. Skin rashes of an erythematous, eczematous or pustular type have occurred. Albuminuria is occasionally found. Glycosuria has been described, but it is rare. Tremor, affecting the muscles of the tongue and face, the arms and hands, and later the legs and trunk, occurs. It is of a fine type, but may be interrupted every few minutes by coarse shaking movements, known to the layman as the "hatters' shakes." The severe mental symptoms known as erethism have been rare since silver took the place of mercury in mirror making. The man affected is easily upset and embarrassed, loses all joy of life, and lives in constant fear of being dismissed. He has a sense of timidity and may lose self-control before strangers. He may be obliged to give up work because he can no longer take orders without losing his temper. Drowsiness by day, depression, loss of memory and insomnia may occur but under modern industrial conditions hallucinations, delusions and mania are rare.

Diagnosis.—This is made by the history and symptoms; but it should be confirmed by analytical tests. Mercury is excreted in small amounts in the fæces. The greatest care should be taken that no mercurial preparation is being administered medicinally during the test. The fæces are collected, and the organic matter destroyed by treatment with hydrochloric acid and potassium chlorate. The resulting solution is submitted to electrolysis, and the mercury present is deposited on a gold kathode, from which it may be dissolved and submitted to the usual chemical tests.

Treatment.—In the manufacture of clinical thermometers and in laboratories where mercury is handled extensively, the benches must be covered with a smooth and impervious surface sloping in such a way as to drain the mercury into a suitable receptacle at the lowest point. The walls and floors should be of impervious material, and the floor cleansed at the end of each day's work. Thermometers must not be filled without suitable exhaust-ventilation for the removal of mercury vapour. Overalls, mess-rooms, and washing facilities are provided. The mouth and pharynx are frequently rinsed with a mouth-wash, and the teeth cleaned with a soft toothbrush and a dentifrice. Periodical medical and dental examination can achieve a great deal, especially by emphasis on the proper hygiene of the mouth. Cavities in carious teeth are filled, sharp angles smoothed, and stumps and teeth irremediably decayed extracted. In the felt-hat trade the workshops must be well managed and spotlessly clean. Efficient exhaust-ventilation must be applied to remove the particles of fur and all vapours of mercury compounds at the source of origin. The failure of chemists to find an efficient substitute for mercuric nitrate in the felting of fur remains a blot upon modern industrial practice, for although the number of cases of poisoning in Great Britain is now negligible there are many elsewhere. Soviet Russia has had the courage to use potash in place of mercury, but this

produces felt of inferior quality. A workman affected by mercurial tremor must give up his work, and abstain from alcohol. Stomatitis should be treated by the use of the toothbrush, mouth washes and dental extractions when necessary. In cases of medicinal poisoning saline aperients should be given daily to promote the free elimination of mercury by the colon.

(3) Poisoning by Mercury Fulminate

Mercury fulminate is handled in explosives factories where detonators and percussion caps are made. In those processes where the fine dust of this substance falls upon the skin dermatitis follows. The susceptibility of some individuals is such that they cannot stand the dust for a day, whereas others only suffer in warm weather. As a rule the cases of "fulminate itch," as they are called in the trade, are slight. The face, eyelids, neck and forearms are attacked by erythema, accompanied by itching, swelling and œdema. Papules break out on the inflamed areas, and may become vesicles, bullæ and pustules. A pustular folliculitis commonly develops on the hairy parts of the skin. If the fulminate lodges in a crack or abrasion of the skin it may act as a corrosive, causing small painful necrotic lesions on the hands which last about a fortnight. The operatives call them "powder holes." Recovery takes place in from 1 to 2 weeks and is accompanied by desquamation. Inflammation of the conjunctivæ and mucous membranes of the nose and larynx may occur.

In the manufacture of mercury fulminate meticulous attention should be paid to detail in all matters of cleanliness in the entire plant. Where fumes are given off as the result of small explosions they must be removed by means of mechanical ventilation. All persons employed should be provided with well-fitting overalls, caps, indiarubber gloves, and if necessary respirators. Washing accommodation must be available close to the workroom, and a separate towel provided for each worker. The hands and arms are washed before meals and before leaving work in a 10 per cent. aqueous solution of sodium thiosulphate. A lanolin ointment is rubbed into the skin after washing. For the conjunctivitis a 2 per cent. solution of sodium thiosulphate as an eyewash has been beneficial.

(4) Poisoning by Organic Mercury Compounds

Fungicidal dusts containing organic mercury compounds are used extensively in agriculture to prevent certain smut diseases of cereals. For some years mercurial derivatives of the phenyl and tolyl series have been manufactured without any mishap worse than an occasional burn on the skin. Poisoning by inhalation of methyl mercury compounds leads to involvement of the nervous system in a unique way, salivation, stomatitis and erethism being absent. There is severe generalised ataxia, dysarthria and a gross constriction of the fields of vision, memory and intelligence being unaffected. In severe cases the patient remains crippled, and unable to stand or to speak intelligibly. The condition has been reproduced experimentally. Rats and monkeys were exposed to the vapour of methyl mercury iodide and they became grossly ataxic. Histological studies showed myelin degeneration in the peripheral nerves, posterior roots and dorsal columns.

In the manufacture of organic mercury compounds elaborate precautions must be taken to prevent contact with the skin or inhalation. The use of gloves and respirators is not enough. The whole process of manufacture, including the final packing of the dusts, must be carried out mechanically in closed apparatus. The farmer should be protected both by warnings that mercurial dressings are poisonous and by schemes whereby he can obtain from the seed merchant seed already dressed. The seed merchant must dress the seed in a completely closed apparatus. The ataxia and dysarthria of methyl mercury poisoning must be treated by re-educative movements, persuading the patient to walk on chalked lines. An expert in charge of a speech clinic with great patience and the use of a mirror should teach the workman to speak. With great perseverance in some cases he may be taught to use knife and fork, a pencil and even a typewriter.

W. H. WILLCOX.
DONALD HUNTER.

MANGANESE POISONING

Ætiology.—Manganese is used in the manufacture of dry batteries and in the pottery, soap and colour industries. Cases of poisoning have followed upon the inhalation of excessive amounts of dust in the grinding, sieving and packing of manganese ores, and in the manufacture of manganese steel in which the metal is first fused in the electric furnace.

Pathology.—Susceptible individuals are few. There is a similarity between this form of poisoning and progressive lenticular degeneration, except that in manganese poisoning the condition remains stationary or improves when exposure to manganese dust ceases. Histological studies on necropsy material have shown degenerative lesions of the nerve cells, particularly in the globus pallidus, the lenticular nucleus and the caudate nucleus. The fact that histological lesions have been found in the liver makes still closer the connection between poisoning by manganese and progressive lenticular degeneration. The condition has been reproduced experimentally in monkeys by administering manganese chloride by intraperitoneal injection. The animals developed choreic movements, passed into a state of rigidity, and finally developed tremor resembling paralysis agitans. Gross morbid changes were found in the lenticular nucleus and liver. The experiments afford an explanation of the symptoms in most of the cases described. The extrapyramidal motor system is clearly picked out by the poison, hence the rigidity, difficult gait, retropulsion, propulsion, mask-like facies, sleepiness, tremor, and uncontrollable laughter.

Symptoms.—The symptoms include languor and sleepiness, low monotonous voice, mask-like facies, involuntary movements varying in degree from a fine tremor of the hands to gross rhythmical movements of the arms, legs, trunk and head, cramps in the calves, retropulsion and propulsion, unsteady gait, and occasionally uncontrollable laughter or crying. There is no disability except in the nervous system.

Prognosis.—Although men seriously poisoned are life-long cripples, the condition is not lethal.

Treatment.—Manganese poisoning can be prevented by wearing res-

pirators wherever dusts or vapours are encountered. Personal hygiene is important, and the worker must wear protective clothing and gloves, since the occurrence of skin absorption is established. Local exhaust ventilation should be applied, both at the furnaces to remove fumes and at the packing and sieving apparatus to remove dust. These measures are attended with good results, for it has been found that when they were applied in one particular factory they removed all risk of poisoning encountered by the workers over a period of 6 years.

DONALD HUNTER.

CARBON MONOXIDE POISONING

Carbon Monoxide, or Carbonic Oxide (CO), is a very poisonous gas. If present in the air breathed in an amount equal to 0·2 per cent. it is capable of destroying life; while an atmosphere containing 0·05 per cent. of carbon monoxide gives rise to definite symptoms of poisoning.

Ætiology and Pathology.—When carbon is burnt in a limited supply of oxygen, carbon monoxide is produced in varying amount. *Domestic poisoning:* Charcoal fires and braziers give rise to considerable amounts of CO. Certain types of water heaters and slow combustion stoves are common sources of production of the gas, which may give rise to poisoning if the ventilating flues are inadequate. In lime kilns there is evolution of CO_2 and CO. The exhaust fumes from motor-cars and petrol-burning engines contain approximately 6 per cent. of carbon monoxide. The commonest source of carbon monoxide poisoning is from coal gas which is used for illuminating or heating purposes. Coal gas contains normally a percentage of from 4 to 10 per cent. carbon monoxide, and it often approximates to the latter figure. It is a common cause of death either from accidental leakage of pipes or from purposive exposure due to turned-on taps. Carbon monoxide occurs in the smoke and fumes from fires with inadequate chimney ventilation. It is important to remember that the products of combustion of gas stoves and gas fires contain an appreciable amount of carbon monoxide. The flues from these are often quite inadequate completely to carry away the products of combustion, in which case the gas stoves and gas fires, when used, give rise to the addition of carbon monoxide to the air of dwellings and so are a source of ill-health or chronic CO poisoning. *Industrial poisoning*: This occurs from the fumes from blast furnaces, in iron smelting, and in blasting operations in mines. In coal mines the explosions from coal dust, or inflammable gases, lead to the production of carbon monoxide (after-damp). *Water gas* is prepared by passing steam over red-hot coke, and contains upwards of 30 per cent. CO. It is used for heating purposes, and is sometimes added to coal gas before its distribution. It is very poisonous and, owing to its slight smell, is very dangerous unless mixed with odorous gases. *Producer gas* is prepared by passing a mixture of steam and air over red-hot coke in retorts. It is used for heating the coal retorts for the preparation of coal gas. Producer gas is a mixture of carbon monoxide, hydrogen and nitrogen, and is similar in composition and properties to water gas, and may contain as much as 30 per cent. of carbon monoxide. Industrial dangers

also arise from leakages in the plant and from the process of charging the producer-gas retorts.

Action of carbon monoxide.—Carbon monoxide has 220 times the affinity for hæmoglobin that oxygen has. If respired, it will, therefore, more or less completely displace the oxygen from its combination with the hæmoglobin of the red cells. This prevents oxygen being carried in requisite amount by the red cells to the tissues of the body, which thus become deprived of the oxygen necessary for their vital functions. The extent to which the hæmoglobin is saturated with carbon monoxide depends upon the percentage of the latter in the air breathed. When the hæmoglobin becomes one-third saturated with carbon monoxide, definite symptoms of poisoning occur, and when the saturation exceeds 50 per cent. there is grave danger of a fatal issue. It is important to note that carbon monoxide is a tissue poison. It does not act simply as an oxygen depriver to the tissues, but undoubtedly has in addition a narcotic action upon them. This is best illustrated by considering the serious symptoms of narcosis (muscular paralysis and loss of consciousness) which occur in a person in whom 50 per cent. saturation of the hæmoglobin with carbon monoxide exists. These symptoms far exceed in gravity those of a person possessing only 50 per cent. of hæmoglobin as the result of anæmia from disease or hæmorrhage. Carbon monoxide acts as a tissue poison especially to the nervous system, but there is evidence to show that it acts on all the tissues of the body, notably the cardiac muscle, and may cause degenerative changes in them.

Post-mortem appearances.—The external appearances are characteristic, the cheeks and lips and post-mortem stains appearing cherry-pink in colour. On opening the body, the blood, muscles and internal organs have a characteristic cherry-pink colour. The lungs may show areas of consolidation due to broncho-pneumonia. Small hæmorrhages may be visible, and œdema is common. The brain shows congestion and œdema, and small punctiform hæmorrhages may be found in the cortex and basal ganglia. The heart may show degeneration of the cardiac muscle and punctiform hæmorrhages beneath the pericardium. In some cases of carbon monoxide poisoning putrefaction is much delayed.

Symptoms.—The onset of carbon monoxide poisoning is usually very insidious, since the gas is odourless and any smell of an atmosphere containing it is due to the presence of other gases or vapours having a characteristic odour. Also the gas may be respired freely without any irritation to the air passages. Premonitory symptoms are giddiness, ataxic gait, a swimming sensation, headache or a sensation of heaviness or constriction in the head, noises in the ears, and a feeling of oppression in the chest. Sometimes nausea and vomiting occur. The onset is, however, often sudden, and this is likely to be so when the percentage of carbon monoxide is relatively high. In these cases, the first symptoms may be sudden collapse, with loss of consciousness, and this is associated with complete loss of power of the muscular system. In subacute cases the symptoms may resemble those of acute alcoholic poisoning. An analysis of the blood would at once reveal the exact diagnosis.

Cardio-vascular symptoms, such as violent beating of the heart and throbbing of the blood vessels, occur. The blood pressure rises at first, and the pulse is full and may not be increased in frequency. Muscular weak-

ness and drowsiness quickly supervene in severe cases, and the patient falls unconscious. In the condition of coma the blood pressure falls and the pulse becomes rapid and small. The conjunctivæ become hyperæmic and the eyes have a staring appearance, the pupils being partially dilated, and do not react to light. The complexion has a cherry-red appearance. Froth may be present on the lips. The breathing is stertorous. The temperature is usually subnormal in the early stages of coma, but is sometimes raised above the normal in the later stages. There is relaxation of the sphincters in severe cases. Broncho-pneumonia may develop if the coma is prolonged for more than a few hours. When the state of coma lasts only for an hour or two, the recovery may be rapid. It is very important to remember that though the muscular power recovers quickly, the tissues of the body have been submitted to a serious acute toxæmia. In all cases where coma has occurred, careful after-treatment is essential, since thereby the occurrence of after-effects such as weakness or paralysis, or mental disorder, may be avoided.

Diagnosis.—In all cases, at the earliest opportunity, a specimen of blood should be obtained for analysis. About 10 c.c. are removed from a convenient vein of the arm, and placed in a small test-tube so as almost to fill it, and a cork inserted. This can then be sent to the laboratory for analysis. It should not be shaken or exposed to the air. The carbon monoxide present in the blood is most conveniently estimated by means of Hartridge's reversion spectroscope. The percentage of carbon monoxide present is of value not only for diagnosis but for prognosis.

It may be remarked that a record of the blood analysis in cases of carbon monoxide poisoning would be of great interest and value for research purposes.

Treatment.—Elimination of the carbon monoxide is best effected by the ventilation of the lungs with pure air and oxygen.

Immediate removal of the patient to an uncontaminated atmosphere is the first step. Onlookers should not be allowed near the patient. If removed to a room, the windows and doors should be widely open and a free current of air encouraged. Complete rest is absolutely necessary, and attempts to keep the patient on the move should be forbidden. The patient should be lying flat, and all constricting clothing round the neck and chest should be loosened or removed. Care should be taken that the air passages are free, and any froth or saliva wiped away from the mouth or nose. If necessary, the tongue should be pulled forwards with tongue forceps. In some cases, especially if convulsions have occurred, a gag may be required to keep the mouth open. Warmth of the body is important, and blankets and hot-water bottles should be used.

Artificial respiration is of great value, as this enables oxygen to reach the alveoli of the lung. The method most suitable is Sylvester's, for this permits of free access of fresh air to the air passages and is more convenient for the administration of oxygen. The upper extremities are moved upwards to a fully extended position above the head and kept there for two seconds, they are then lowered to the sides of the chest and firmly pressed against the ribs for about two seconds, the double movements being repeated about fifteen times per minute. Oxygen and 5 per cent. carbon dioxide should be administered without delay. For its efficient administration a cylinder,

with a suitable regulating valve tap, and a B.L.B. mask are required. If no cylinder containing the mixture be available a sparklet bulb containing CO_2 may be used in conjunction with an oxygen cylinder. A special metal perforator with tube attached is available for the purpose of perforating the sparklet and admitting the carbon dioxide at a desired rate by means of a rubber tube. The rubber tube is placed under the oxygen mouthpiece, so that the mixture of oxygen and carbon dioxide can be conveniently administered. This method of administration is easily and conveniently effected and is entirely free from any risk. When the respiration of the patient has become normal, pure oxygen should be administered for about 3 hours, with short intervals for feeding. This will be of value in getting rid of the carbon monoxide from the blood of the patient.

Atropine sulphate, gr. $\frac{1}{100}$, may be given hypodermically, and repeated, if required. In severe cases it may be necessary to treat collapse by means of subcutaneous normal saline (1 pint), or possibly blood transfusion.

After-Treatment.—In mild cases, where coma only lasts a short time, it is important that the patient should be kept completely at rest in bed and under medical supervision for a few days. In severe cases, where coma has been prolonged for several hours, complete rest in bed under medical supervision for 2 or 3 weeks or more will be required, since otherwise there is a danger of after-complications. A certain proportion of cases that have been severely poisoned develop confusional insanity. Prognosis for life is then good, but the mental prognosis is poor.

W. H. Willcox.
Donald Hunter.

POISONING BY COAL-TAR DERIVATIVES

The coal-tar derivatives are so numerous and complex that it is difficult for the toxicologist to keep pace with the chemists who produce them. The following compounds will be discussed: benzene, mononitrobenzene, dinitrobenzene, phenylenediamine, trinitrotoluene, dinitrophenol and aniline. It is sometimes possible to predict from the chemical composition of the simpler members of the group what their physiological action is likely to be. Addition of a nitro- or nitroso-group usually produces a more toxic compound, but it does not follow that toxicity will continue to increase as more nitro-groups are added. Thus, 1–2–4 dinitrophenol is toxic, whereas trinitrophenol is practically harmless. The position of the substituent groups in the benzene ring has a great effect on the toxic action. Thus, the toxic properties of 1–2–4 dinitrophenol are not shared by any of the other isomers. When a nitro-compound is reduced to an amine, as when nitrobenzene is reduced to aniline or nitrotoluene to a toluidine, the toxic characteristics remain much the same, but the intensity of the action is lessened. Sulphonation renders a compound non-toxic; as soon as aniline is sulphonated it ceases to give trouble. The entrance of chlorine into an aromatic compound does not increase the toxicity, as it does in the case of an aliphatic compound. In fact, chlorbenzene is less toxic than benzene.

1. Benzene

Coal-tar benzene or benzole is obtained as a by-product from the distillation of tar in the manufacture of coal gas. It is the most interesting of the industrial solvents, and with the exception of tetrachlorethane the most dangerous. It must not be confused with benzine, which is unfortunately pronounced in the same way. Benzine is derived from the distillation of petroleum and is non-toxic. Coal-tar benzene has two fields of application in industry: (1) where it is handled in large quantities in closed mechanical systems, as in the distillation of coal-tar, the blending of motor fuel and in chemical industry; and (2) where it is used as a solvent, as in the rubber industry, artificial leather manufacture, the dyeing and cleaning industry, the manufacture of paints, varnishes, celluloid, artificial manure and glue.

Acute benzene poisoning usually occurs as the result of the breaking of distilling apparatus, or in the cleaning of tanks. In slight cases there is giddiness, and a stage of excitement; in severe cases these symptoms may be followed by convulsions, coma and death. Benzene sinks into the metal of tanks. It is therefore necessary to forbid men to enter such tanks until they have been washed clean and exposed to the open air for many days. Even then a workman lowered into such a tank must be equipped with body belt, life-line and breathing apparatus communicating with a hose to the exterior. In the stage of excitement the victim may shriek, sing madly and fight with the rescuer, who, on account of his greater exertions, runs more risk than the rescued.

Chronic benzene poisoning has always been very rare in Great Britain. Speaking for the whole world, however, it was at one time the most important industrial poison after lead. Benzene poisoning may begin with giddiness, nausea, anorexia, weakness and nervousness. These symptoms are followed by progressive anæmia, with hæmorrhagic manifestations, such as bleeding gums, epistaxis, menorrhagia, purpura and visceral and retinal hæmorrhages. Ulcers or gangrenous patches on the lips, fauces and pharynx are common. Although poisoning may occur only after many years' exposure there have been fatalities after a few weeks' exposure. The victims of industrial poisoning often constitute a small minority of the workers; a single susceptible individual may contract fatal poisoning in an environment which does not give rise even to mild poisoning in others. The factors responsible for the great variations in susceptibility are largely unknown, but in general women, especially young women, are more susceptible than men. Changes in the blood may begin from 2 days to 1 month after the first exposure, according to the amount absorbed, and they may progress or even develop after exposure has ceased. Acclimatisation to the vapour of benzene does not seem to occur, and it is doubtful whether any concentration greater than zero is safe over a long period of time.

The bone marrow is attacked, and it may be aplastic, normal, hyperplastic or leukæmic, the corresponding changes being reflected in the peripheral blood. In the early stages of poisoning there may be little or no evidence of damage to the red cells but only purpura with leukopenia and granulopenia. The total leucocyte count may fall to a very low level; in fact, the white cells may almost disappear. A count of one thousand per c.mm. is common. In some cases the granular leucocytes fall as low as

10 per cent. The bleeding time may be increased to half an hour, with a corresponding drop in the platelets. The red cell count may fall as low as three-quarters of a million per c.mm. Splenomegaly may appear in protracted cases of poisoning. Myeloid leukæmia, confirmed by post-mortem examination, has been found in several cases. Necropsy usually shows aplasia of the bone marrow. Hæmorrhages may be found in the skin, pericardium, pleura, alimentary tract, meninges, bladder and uterus. Gangrenous stomatitis and even necrosis of the gastric mucosa have been recorded. Benzene cannot be discovered in the body after death.

Benzene is so toxic that its substitution wherever possible by other solvents which are harmless is in preventive treatment the method of first choice. In all processes involving the presence of benzene the value of frequent periodical medical examination, including examination of the blood, has been proved by experience. The more complete and effective the prevention of the escape of vapours into the workrooms and the more efficient the daily supervision of the ventilating apparatus, the less is the necessity for periodical medical examination.

In acute benzene poisoning the usual methods of resuscitation are used: rest, warmth, artificial respiration, administration of oxygen and carbon dioxide mixture, and injection of coramine as a respiratory stimulant. The patient should be prevented from returning to work too early.

Cases of chronic benzene poisoning must be treated by repeated blood transfusions and it must be remembered that the toxic influence may persist even after removal from exposure. The results of treatment are so poor as to convince all who have studied the subject that the use of benzene in industry must be ruthlessly suppressed, except where the process used is entirely enclosed. Fortunately in Great Britain it has been possible to do this.

2. Mono-nitrobenzene

Mono-nitrobenzene (oil of mirbane; artificial oil of bitter almonds) is used in the manufacture of aniline, in perfumery and as a flavouring agent, being the chief substitute for oil of bitter almonds. It is sometimes taken as an abortifacient, and on several occasions 15–25 drops have proved fatal, especially if the poison is taken with alcohol. The stomach should be washed out repeatedly with water until the returned fluid no longer smells of nitrobenzene. Purgatives should be given. In factories death has taken place from absorption through the skin, where the oil has been spilled on the clothing. The victim of such an accident should be stripped promptly of his clothes, sponged with weak acetic acid or vinegar, and provided with a shower bath and clean clothes. The symptoms vary according to the acuteness of the poisoning. Pallor appears, quickly followed by lividity. Unconsciousness occurs with great rapidity, perhaps in 20 minutes. The patient is generally deeply cyanosed, and the blood is dark and viscid, and will sooner or later show the spectrum of methæmoglobin. Death occurs in coma, or recovery takes place after a variable period of unconsciousness. However, nausea and vomiting may begin again after a few days, and toxic jaundice appear. The blood picture is that of anæmia with granular degeneration of the red cells (stippling), and sometimes the presence of nucleated red cells. In severe anæmia a blood transfusion may be considered.

3. Dinitrobenzene

Dinitrobenzene is used in the manufacture of dyes, and is itself an important explosive. It is a solid, and in consequence poisoning develops less rapidly and is less severe than in the case of mono-nitrobenzene. Poisoning occurs amongst men who either shovel or melt dinitrobenzene. In a mild case there is a sense of pressure in the head, which increases to a violent throbbing headache, giddiness and dyspnœa. In severe cases the face is deeply cyanosed; the lips, tongue and ears are deeply purple; and there are nausea, sometimes vomiting, abdominal pain, a staggering gait and extreme weakness. An attack rarely occurs during work; the man is usually overcome some hours after he has left the plant. Cyanosis occurs, and is accompanied by anæmia with marked stippling of the red cells. Methæmoglobin, hæmatoporphyrin, hæmoglobin, and even albumin have been found in the urine. The smoky colour of the urine may be noticed by the men themselves soon after their first contact with nitrobenzene or aniline. Only very rarely does toxic jaundice occur. It is well known in industry that cases of poisoning are more frequent in hot weather than during the colder seasons of the year. Lack of care and unclean habits are predisposing causes. Those who do not change their working clothes on returning home may sit before the fire and absorb the poison from the evaporation of crystals or from the material in solution on their clothing. Absorption from the alimentary canal is more rapid if the stomach is empty, and it is therefore desirable that men should take a meal before they work. Alcohol undoubtedly favours absorption, and several instances are on record in which poisoning has supervened after indulgence in ordinary amounts.

4. Phenylenediamine

Phenylenediamine is used for two similar purposes; for dyeing hair black and as a dye for furs. It is well known that it may cause dermatitis and sometimes asthma in susceptible persons. Its systemic effects are much rarer and have received less attention. Hairdressers handling the dye have suffered from attacks of weakness and vomiting, with intense violet cyanosis of the lips and face. In unusually susceptible individuals toxic jaundice has occurred, followed by death from hepatic insufficiency after about 6 months. At necropsy the liver is small and shows the changes of subacute atrophy with regeneration nodules. Persons handling the dye should wear rubber gloves. Avoidance of exposure removes the cyanosis completely.

5. Trinitrotoluene

Trinitrotoluene is handled mainly in the filling of shells. The first symptoms of poisoning are drowsiness, headache, nausea, loss of appetite, epigastric pain, vomiting and giddiness. There is some cyanosis of the lips, followed by dyspnœa with marked drowsiness and staggering gait. Dermatitis in the form of a diffuse erythema sometimes occurs on the dorsal surfaces of the wrists, and on the face and neck. The symptoms come on gradually after several days' or weeks' work, or they appear on a hot day

after a few hours' work and cause collapse. If cyanosis occurs in one in ten of the workers, toxic jaundice probably affects one in five hundred. The greatest incidence of jaundice is in the third month of employment. Premonitory symptoms, such as drowsiness, giddiness, depression, and dark urine are sometimes present, but the onset is often quite sudden. Sometimes a latent interval occurs between removal from exposure and the onset of jaundice. The prognosis is always uncertain, but grave symptoms of hepatic insufficiency sometimes appear rapidly. The mortality is 25 per cent. The morbid appearances are those of yellow and red necrosis of the liver, with great reduction in its size and weight. The necrosis of the liver cells is associated with infiltration and subsequent fibrosis resembling ordinary portal cirrhosis. Aplastic anæmia sometimes occurs among trinitrotoluene workers, but its incidence is very small. The latency of the blood changes is even longer than the latency of the jaundice, for it is found that anæmia can develop as long as 9 months after exposure to trinitrotoluene has ceased. The anæmia is usually, if not always, fatal. At necropsy fatty marrow is found throughout all bones. There is an excess of iron pigment in the liver, and multiple hæmorrhages are found in the tissues. The skin is the main channel of absorption. Experience in industry goes to show that when a poison is absorbed by this route the application of preventive measures is most difficult; trinitrotoluene is no exception. By the end of the War of 1914–1918 the risk of poisoning had been greatly diminished, not by any single precaution but by the combination of several, of which alternation of employment, periodical medical examination, ventilation and clean working conditions were the chief. Success was not achieved until mechanical means were substituted for the hand filling of shells, combined with measures of cleanliness which were so precise as to prevent the contamination of the outside of the shell by trinitrotoluene.

6. Dinitrophenol

It is the 1–2–4 isomer of dinitrophenol which has toxic properties. These were revealed in the War of 1914–1918, especially in French shell-filling factories. The illness begins with lassitude, and the worker may notice yellow patches on the covered parts of the skin due to excretion in the sweat of dinitrophenol. Tremor, excitement and intense thirst follow, and the face may be slightly cyanosed. In severe cases orthopnœa, hyperpyrexia and convulsions set in, and death occurs in a condition resembling uræmia. The urine is of an orange yellow colour, and gives a diazo reaction, which serves both quantitatively and qualitatively to determine the amount of the poison absorbed, and so to give a clear indication as to when suspension and transference to other work are necessary. At necropsy no pathognomonic feature is found; there is no atrophy of the liver. The workmen must be provided with a complete set of underclothing and overalls into which they change from their working clothes, a separate cubicle being provided for each man. Well designed exhaust ventilation must be applied locally to take away the fumes in the melting of the compound and also in the filling of shells. Any dust that collects around the margin of the shell must be removed by a vacuum cleaner.

7. Aniline

Aniline is a colourless oily liquid which darkens on exposure to light or air. It is handled in the manufacture of dyes, in the dyeing and cloth-pressing industries, in the extraction of resin and in the rubber industry. Aniline poisoning arises usually from inhalation, but absorption through the skin and less frequently inhalation of dusts of aniline compounds may cause it. Care must be taken to change the clothes at once whenever they are splashed with aniline. Men must avoid entering chambers filled with its vapour. The symptoms of aniline poisoning are similar in all respects to those of nitrobenzene poisoning. The convenient term *anilism* may be used to cover the symptoms produced by most of the nitro- and amino-derivatives of benzene.

In *acute aniline poisoning* there is headache, weakness, difficulty in breathing, cyanosis, loss of power in the limbs and giddiness. In severe cases the cyanosis is more intense and prostration occurs with a cold moist skin, small pulse, air hunger and even death in coma. When recovery occurs it is often gradual and may be accompanied by increased frequency of micturition. In *chronic poisoning* the workers show slight cyanosis, secondary anæmia, and sometimes sleeplessness, headache, giddiness and abdominal discomfort. In hot weather practically all the men exposed to aniline and similar compounds in a dye works show cyanosis.

The manufacture of nitrobenzene, and the reduction of nitrobenzene and nitrotoluene to aniline and toluidine must take place in closed vessels. Even so, escape of small quantities of aniline into the atmosphere is very difficult to prevent unless ample ventilation is provided. Therefore in addition to the technical regulations there must be insistence on cleanliness of the workrooms, personal cleanliness on the part of the workers and provision of baths and changes of clothing. Contact with aniline and nitrobenzene, especially on the skin, and also the spilling and splashing of these fluids must be carefully avoided. All workers must be strictly instructed as to the symptoms of nitrobenzene and aniline poisoning, and the right steps to take if poisoned. Regular medical inspection of workmen is desirable.

Workers, and especially those newly employed, must be under supervision in order that assistance may be rendered them on the first signs of poisoning. Medical assistance should be within easy reach. Systematic instruction should be given in first-aid methods, and in the use of apparatus for oxygen and carbon dioxide inhalation. The possibility of skin absorption must always be borne in mind. A victim whose skin or clothing has been splashed with aniline may turn blue in the face and begin to stagger. Someone may take him out to the fresh air or administer oxygen, when what he needs most is to have his clothes stripped off and be given a bath. Workers entering stills and similar chambers should always be equipped with breathing apparatus and a supply of oxygen. Other aids, such as safety belts which are held by helpers, involve certain risks, especially as the rescuer is easily induced to spring to the assistance of his unfortunate mate without the necessary breathing equipment. The frequency of such accidents calls urgently for the use of breathing apparatus.

POISONING BY CHLORINATED HYDROCARBONS

The rapid growth of the moulded plastics and cellulose lacquer industries has led to the extensive use of many new solvents, most of which were little more than chemical curiosities before about 1925. Amongst these are the chlorinated hydrocarbons which have flooded the market largely because the alkali industry requires an outlet for its by-product chlorine. The various members of the group are useful as refrigerants, as degreasers of metals, fire-extinguishers, cleansers of textiles, solvents for rubber and thinners of cellulose lacquers. They are non-inflammable, non-combustible, and non-explosive, but they are far from harmless in their effects on the human body. The action of carbon tetrachloride has been extensively studied because of its use in hookworm therapy. Tetrachlorethane dramatically attracted attention in the War of 1914–1918, and a mass poisoning from leaking refrigerators in Chicago has led to an increase in knowledge of the action of methyl chloride. Trichlorethylene has been studied because of its extensive use in dry cleaning.

1. Methyl Chloride

Men working in chemical plants or employed upon making, installing or repairing refrigerators may be exposed to methyl chloride. Symptoms of poisoning include giddiness, weakness of extremities, nausea, vomiting, restlessness, followed by somnolence, and then by dimness of vision, which may not clear up until 14 days after removal from exposure. Later there is some rise of temperature, pulse, and respiratory rate, usually with oliguria and occasionally with suppression lasting up to 48 hours. Evidence of acute nephritis is found in about half the cases. Anæmia may be found, the red cells dropping as low as 3 million per c.mm., and the hæmoglobin as low as 50 per cent. The death-rate is as high as 35 per cent.

2. Carbon Tetrachloride

Carbon tetrachloride is used in industry as a solvent for fats and rubber, for dry cleaning, for cleaning oil from machinery, and under the name pyrene as a fire extinguisher. Acute and sometimes fatal poisoning has occurred from the anæsthetic effects of carbon tetrachloride used as a dry shampoo for the hair. Men exposed to the vapour sprayed from pyrene fire extinguishers in confined spaces have suffered from oliguria and jaundice. In animal experiments carbon tetrachloride has been shown to cause necrosis of the liver. In man it may attack both liver and kidneys, but in most clinical histories so far published the symptoms of renal injury overshadow those of hepatic injury. The early stages of the illness are characterised by persistent headache, nausea, vomiting, diarrhœa and tenderness over the liver. Such symptoms are often followed by oliguria, suppression of urine and uræmia. The blood urea may rise to 300 mg. per 100 c.c. and the patient, though practically moribund, may suddenly develop polyuria and recover even after almost complete anuria lasting 10 days. When the liver is attacked recovery may follow an attack of jaundice lasting as long as 2 months.

In the treatment of cases rendered unconscious by acute poisoning, it is important that the patient should not be placed upon the floor of the room where the accident occurred, for the vapour is five times denser than air and therefore accumulates on the floor. Chronic poisoning should be treated by glucose drinks, together with large doses of calcium lactate up to 15 grammes a day. If necessary calcium gluconate may be given by intramuscular injection.

3. Tetrachlorethane

Tetrachlorethane is the most dangerous of all the chlorinated hydrocarbons, being nine times as toxic as carbon tetrachloride. It is a very good solvent for cellulose acetate, which, being non-inflammable, is used for purposes for which cellulose nitrate (celluloid) is not adapted. Cellulose acetate was the chief constituent of the dope used as a waterproof coating for the wings of aeroplanes in the War of 1914–1918, and it is now used to make non-inflammable cinema film. The symptoms of poisoning are general malaise, loss of appetite, nausea, headache and constipation. After several days or even weeks, jaundice develops and vomiting is then likely to become more marked. In fatal cases necrosis of the liver is found in the form of acute red and yellow atrophy. In one case the liver weighed only 19 oz. The blood changes in mild poisoning consist of an increase of large mononuclear cells up to 40 per cent., with a slight elevation of the white count. Blood counts have been taken in order to detect early poisoning. Elaborate exhaust ventilation in factories and workshops fails to prevent toxic jaundice. It is therefore necessary to use a harmless solvent, such as amyl acetate in place of tetrachlorethane.

4. Trichlorethylene

Trichlorethylene is a non-inflammable solvent employed extensively in dry cleaning. It has assumed an important place in the list of fat and rubber solvents, displacing to some extent carbon tetrachloride. Trichlorethylene has a powerful narcotic effect. The workman affected is usually found unconscious on the floor, and if there has been prolonged exposure to a large dose the effects may be fatal. Chronic exposure has been held responsible for paralysis of the sensory fibres of the fifth nerve, and also for retrobulbar neuritis followed by optic atrophy. An indirect form of injury to the eye sometimes occurs when a foreign body lodges in the cornea and produces ulceration. The workman is not aware of the presence of the irritant substance, because the cornea has been rendered insensitive. Apparently trichlorethylene is not so likely to attack the liver as tetrachlorethane. Toxic jaundice and albuminuria have only rarely been recorded. Dry cleaning establishments employing trichlorethylene should be provided with efficient exhaust ventilation. When solutions containing trichlorethylene are applied to the interior of closed vats the men should work in pairs, relieving each other frequently. The man in the enclosed space should be provided with a lifebelt and also with an apparatus through which he can breathe air from outside.

Donald Hunter.

ACKEE POISONING

Synonym.—Vomiting sickness of Jamaica.

Definition.—A frequently fatal disease, especially affecting children in the West Indies, characterised by vomiting and nervous symptoms due to eating the unripe ackee fruit.

Ætiology.—Ackee fruit grows on the tree *Blighia sapida* (Sapindaceæ) in the West Indies and West Coast of Africa. The mature fruit is quite harmless, but when eaten in an immature state before the fruit opens, it proves a deadly poison, especially if soup be made from it or other ingredients like rice be boiled in ackee water. The poison is contained in the arilli of the unripe fruit.

Pathology.—Intense fatty changes are found constantly in the liver and to a lesser degree in the kidneys, heart and cortical brain-cells. Hyperæmia of the meninges and other organs occurs, also hæmorrhages in the viscera.

Symptoms.—The patient, who is generally a child and quite well, suddenly commences vomiting some 2 hours after a meal containing unripe ackee fruit and complains of nausea and abdominal discomfort. After 3 or 4 hours of sickness a calm interval ensues, followed by nervous symptoms, including cerebral vomiting, twitching of muscles, convulsions and coma.

Prognosis.—Once nervous symptoms supervene the condition is invariably fatal, the average duration being 12 to 14 hours.

Treatment.—Prevention consists in discarding the immature unopen fruit and in not utilising the water in which ackee fruit is boiled as soup. Alcohol precipitates the poison, and the immediate administration of rum or ether and ammonia as advocated by Scott has reduced the mortality in school children from 90 to 27 per cent.

N. Hamilton Fairley.

FOOD POISONING

Food poisoning occurs when, in mistake for a wholesome food, some article is eaten which is of itself normally poisonous, or rendered poisonous by contamination from outside sources. The former is called Endogenous Food Poisoning, while the latter, which is the ordinary form of food poisoning, is spoken of as Exogenous.

Endogenous Food Poisoning.—The following are examples:

(1) *Poisonous fungi* are sometimes eaten in mistake for edible mushrooms, and dangerous or even fatal results may follow, owing to the presence in them of poisonous substances. Unfortunately there are no simple tests by which the layman may distinguish the poisonous from the harmless species. Experiments in eating new or unfamiliar varieties should never be undertaken.

(*a*) *Amanita phalloides.*—This contains the deadly substance, phallin or amanita toxin. The susceptibility of children is greater than that of adults. The ingestion even of part of a plant may result in poisoning and

the mortality rate is high. After a prodromal period of 4 to 24 hours, acute abdominal pain, vomiting and diarrhœa occur. The vomit and stools may contain blood and mucus. Anuria may occur. Short periods of remission may follow, but usually within a day or two jaundice, cyanosis, and coldness of the extremities develop. In fatal cases coma supervenes. When poisoning is less severe, the symptoms abate in about a week and the patient is well within 4 weeks.

(*b*) *Amanita muscaria.*—This contains muscarine. After a small dose the patient becomes mildly excited, and the fungus is used by Siberian peasants to induce drunkenness. After larger doses the first symptoms appear within 2 to 6 hours. They are salivation, sweating, retching, vomiting and diarrhœa. Giddiness, confusion and hallucinations rapidly follow, and the pupils become contracted and fail to react to light or on accommodation. Amaurosis and diplopia may occur. Although the symptoms are violent the mortality rate is low. In all cases of mild poisoning the prognosis is good.

(2) *Poisonous fish.*—Certain fish, such as those of the species Tetrodon, found in Japanese waters, are normally poisonous, and the same applies to mussels when grown under unhealthy conditions. The symptoms caused by these poisonous foods are those of acute gastro-enteritis, with marked nervous disturbance and collapse.

(3) *Poisonous parts of plants* may be eaten in mistake for foods; for example aconite root for horse radish, or deadly nightshade berries for edible fruit.

Potato Poisoning.—Under certain conditions potatoes may contain a dangerous amount of the poisonous alkaloid solanine. This is produced by the growth of certain forms of bacteria in the tubers, which is likely to occur if, owing to improper storage, sprouting of the potatoes has taken place. The symptoms of solanine poisoning are those of acute gastro-enteritis, associated with nervous prostration and collapse, resembling those caused by poisonous fungi.

In some countries certain harmful vegetables are more or less habitually used as foods. [See (4) and (5).]

W. H. Willcox.
Donald Hunter.

4. Lathyrism—

Definition.—A disease of limited geographical distribution, characterised by spastic spinal paralysis, and caused by poisoning with peas of a vetch of the genus *Lathyrus*.

Ætiology.—The disease, formerly met with in Italy, has been reported from India, especially North Behar and the United Provinces, Algiers, France, Persia, etc. Three species of *Lathyrus* may be associated with poisoning in man: (1) *Lathyrus sativus*, known in India as Khesari dal; (2) *Lathyrus cicera*, the dwarf chick-pea found in France, Italy and Algeria; and (3) *Lathyrus clymenum*, found in Spain, North Africa and the Levant. It is solely confined to countries where different kinds of chick-pea are used for food, but the causative principle is unknown. Young people are specially liable, and men are more affected than women. It occurs as an epidemic amongst the poorest classes in times of great scarcity, when bread is made from a mixture of pea and wheat flour. It may also be eaten as porridge,

or the peas may be boiled with oil and then consumed. Formerly it was attributed to the grain of *Lathyrus sativus* (Khesari dal), but in India, Howard, Anderson and Simonsen failed to demonstrate any poisonous principle. They succeeded in isolating two toxic alkaloid-like bases, vicine and divicine from *Vicia sativa* (akta), an allied vetch, the seeds of which were a common contaminant of Khesari dal and produced symptoms of lathyrism when fed to ducks. It has also been suggested that an absence of vitamin A in the diet may be a contributory factor.

Pathology.—A chronic sclerosis is found in the spinal cord involving the posterior and lateral columns. Possibly a toxic spasm of the arteries of the cord, followed by thrombosis, is the basis of the condition.

Symptoms.—The onset may be insidious with backache, burning pains and weakness of the legs, or it may be sudden, as when after a hard day's work in the rain the patient wakes up with stiff, weak and trembling legs, which feel heavy to lift. These symptoms increase rapidly, and in 10 days walking may be impossible without the aid of a stick. Both legs are usually affected simultaneously, first the calves, then the thighs. Gradually a peculiar gait develops, the patient laboriously progressing by means of a two-handed staff; "the leg bearing the weight of the body is bent at the knee and trembles, while the advancing limb dragged wearily forward and strongly abducted, is planted unsteadily directly in front of its fellow, the toes reaching the ground first." When lying on the back, spasm of the adductors ceases and the thighs can be separated. There is little or no atrophy or loss of muscular tone, the knee-jerks are increased and ankle clonus is marked. Sensation is normal. Incontinence of urine and fæces and possibly loss of sexual power follow involvement of the lumbar enlargement, but the upper extremities are rarely implicated.

Diagnosis.—The occurrence of multiple cases simultaneously and the history of eating chick-peas as food confirm the diagnosis.

Prognosis.—This depends on the stage at which the case is diagnosed: if early, great improvement follows treatment, but in later cases when the cord has become permanently damaged spasticity persists.

Treatment.—Varieties of chick-pea must be avoided as human food, and their abolition stamps out the disease. Avoidance of damp and wet ameliorate the symptoms. A generous diet rich in vitamin A should be given. Massage and electricity are indicated.

5. Atriplicism—

Definition.—A disease associated with local œdema, disturbances of sensibility, and vaso-motor and trophic disorders.

Ætiology.—It occurs in North China. Females are oftener attacked than males; no age is exempt. The condition is due to poisoning with *Atriplex littoralis* (Chenopodiaceæ). Poor people and beggars eat the young shoots, either raw in salads, or in bread.

Pathology.—There are no records of post-mortem examinations with proper histological examinations.

Symptoms.—The onset is sudden, occurring quickly after the ingestion of the plant. First, there is tingling of the fingers, then the backs of the fingers, hands, and later the forearms begin to swell; finally, the face is similarly affected, with violent itching. There may be anæsthesia of the

forefingers and thumbs. Heat sensation is increased. Scratching may cause an ecchymotic condition of some areas, from which eventually the skin is shed in patches, and ulcers may follow.

Diagnosis.—It may be mistaken for Raynaud's disease or erythromelalgia.

Prognosis.—The swellings last for a week or so, but the general health is not affected. The ulcers often become chronic.

Treatment.—All that is required is to avoid eating the plant. Salines, gastro-intestinal disinfectants and, later, tonics may be employed.

G. Carmichael Low.
N. Hamilton Fairley.

Exogenous Food Poisoning.—The contamination may be due to bacteria, or to fungi, or to chemical substances.

A. *Contamination by Bacteria.*

(1) The commonest type of food poisoning is that caused by contamination with Salmonella and other organisms. It is described under the heading "Bacterial food poisoning" (see p. 394).

(2) Specific diseases may be caused by the accidental contamination of food with the specific pathogenic organisms. Thus typhoid or paratyphoid fevers may be caused by milk or oysters containing the specific bacilli; scarlet fever or diphtheria by infection of milk with the specific organism; cholera by the contamination of foods or water with cholera germs, amœbic dysentery by contamination with the specific amœbæ or their cysts, and bacillary dysentery by infection of food with its specific bacilli.

A very common cause of these forms of food poisoning is the handling of food by persons known as "carriers," who are apparently healthy but harbour in their bodies the specific germs of a particular disease, their excreta containing large numbers of the pathogenic organism, so that it is an easy matter for the infection of a food-borne disease to be conveyed by the hands of a "carrier" who is engaged in any way in the handling of food; cooks or milkmen frequently spread infection in this manner. The course of the disease is exactly similar to that described under the diseases in question.

(3) Diseases in animals communicable to man may arise from the consumption of food derived from a diseased animal. Thus the flesh of an animal which has died from anthrax may give rise to this disease in man. Tuberculosis of the mammary glands in the cow will cause the presence of tubercle bacilli in milk, the consumption of which may give rise to human tuberculosis. The flesh of animals suffering from actinomycosis may cause this disease in man. Parasitic diseases, such as trichinosis and tapeworm infections, arise from the consumption of the flesh of animals suffering from these infections. These types of food poisoning are fully described under the diseases in question.

(4) Specific organisms may produce in food highly poisonous toxins, the ingestion of which causes acute and perhaps fatal illness. An instance of this is Botulism (see p. 401).

B. *Contamination by Fungi.*

Ergotism.—The grains of cereals attacked by the ergot fungus (*Claviceps purpurea*) are poisonous, and if consumed give rise to a series of symptoms

known as ergotism. Two types of this condition are known—(*a*) *The gangrenous type.* The onset is with numbness beginning in the extremities, and in the course of a few days gangrene appears in the fingers, toes and sometimes the lobes of the ears and tip of the nose. There is agonising pain which penetrates the affected limb like fire—hence the name, centuries old, *St. Anthony's fire.* Later there is complete anæsthesia in the affected part which becomes livid and then black. (*b*) *The nervous type.* The illness begins with numbness of the hands and feet and twitchings of the muscles of fingers and toes extending to the arms, knees, shoulders, hips and ultimately to the whole body. Severe giddiness, fits, blindness, deafness, delirium and stupidity passing on to dementia are also known. Histological examination shows that the dorsal columns are particularly involved.

C. *Contamination by Chemical Substances.*

Chemical poisons may accidently contaminate foods and give rise to the special symptoms of that kind of poisoning. Examples of this are :

Metallic poisoning resulting from contamination of tinned foods by poisonous metals derived from the container. This is a rare form of poisoning, and is only likely to occur when the contents of the tin are liquid, such as fruit juice, liquefied jelly or soups. If the tin is sound, and care is taken in the canning and in the soldering process, so that the solder does not come in contact with the contents of the tin, the risk of poisoning is negligible. Cases of poisoning have occasionally occurred from the solution of lead, derived from the solder, coming in contact with the contents of the tin. The symptoms of metallic poisoning are described elsewhere.

Arsenical poisoning from the contamination of commercial glucose during its manufacture is described under arsenical poisoning.

Drinking water may be contaminated by lead and give rise to chronic poisoning.

Food preservatives, such as boric acid, formalin, and salicylic acid, if added to foods, may give rise to illness from their toxic effects. The addition of food preservatives to milk is for this reason prohibited by law in this country.

BACTERIAL FOOD POISONING

Synonym.—Ptomaine Poisoning.

This is the form of poisoning caused by the contamination of food with Salmonella and other organisms. The resulting symptoms are caused by the bacterial toxins produced in the food by its contamination. There may also be an actual bacterial infection, should the organisms not be killed in the process of cooking. Since bacterial contamination finds a most suitable culture medium in foods rich in protein, this type of food poisoning usually follows the consumption of meat, fish or milk—especially meat.

It was formerly thought that food poisoning was caused by the presence in food of poisonous alkaloidal substances called ptomaines, produced by putrefactive changes. Neurine and mydaleine are examples of such. It is now known that ptomaines are very rarely, if ever, the cause of food poisoning, but that the usual cause is bacterial contamination of food. It is possible that in the consumption of food highly advanced in putrefaction,

such as high game, ptomaines may play a part in the causation of toxic symptoms, but cases of this kind are uncommon.

Ætiology.—*Predisposing causes.*—Contaminated food has a much more serious effect on persons suffering from pre-existing gastro-intestinal disease. Thus the presence of colitis or enteritis greatly increases the susceptibility of the patient to bacterial food poisoning, and the resulting symptoms are likely to be more severe than in a person previously healthy. Dysentery or post-dysenteric colitis has a like effect. Starvation or malnutrition increases the susceptibility to bacterial food poisoning, and emptiness of the stomach at the time of taking of contaminated food is likely to lead to the earlier onset and greater severity of the symptoms produced. The above considerations help to explain the remarkable fact that sometimes when several persons partake of the same unwholesome food some may suffer from serious symptoms of food poisoning, while others may have only very slight symptoms, or even be unaffected. Young children are much more susceptible. In hot climates bacterial food contamination is likely to be followed by a very rapid development of bacterial poisons. Dust, flies, dirt and insanitary conditions generally are likely to favour the contamination of food with the bacteria of food poisoning. Careful storage of food in refrigerators where it can be kept free from contamination, is most important.

Meat poisoning may be due to contamination of the flesh during the cutting-up process by the butcher, or the meat may be contaminated either in the process of cooking or afterwards, owing to lack of care in storage.

Sausages.—Many epidemics of poisoning have occurred from infected sausages. This can be readily understood, since the process of mincing, which the meat undergoes, renders it liable to contamination. Moreover, in sausages it is easy for unwholesome meat to be used, with little possibility of detection. The fact that sausages are made with raw or only partly cooked meat, and that they are frequently eaten merely smoked, with little or no cooking, still further adds to the risk.

Tinned meat.—This has been frequently the cause of food poisoning. The meat may be contaminated by Salmonella organisms before tinning, and though the process of canning, by the heat applied, may kill the microbes, yet the toxins may not be destroyed, and these will give rise to symptoms of poisoning when the food is eaten. During the War of 1914–1918 tinned meat was consumed in enormous quantities by our troops. Very few cases of food poisoning from tinned meats were recorded, and in those cases where investigations were made the cause of the poisoning was traced to infection of the food after the tins had been opened. Usually the food had been handled by a cook who was a " carrier " of food poisoning organisms. At the present time so much care is taken in the selection of the meat and in the whole process of canning that tinned meat from a reliable source can be regarded as one of the safest foods.

Fish.—Numerous epidemics of food poisoning have been due to eating fish. These have been traced to the contamination of the fish with bacteria of the type already described, and the resulting symptoms have been similar in character. Cooking the fish—boiling or frying—may not entirely destroy the toxins present.

Shellfish.—These are sometimes grown in waters contaminated by sewage containing typhoid and Salmonella bacilli. Mussels, oysters, lobsters,

crabs, etc., have frequently caused severe attacks of food poisoning, and commonly the shellfish appeared perfectly fresh, with no objectionable taste or smell. Under the Ministry of Agriculture and Fisheries in this country special researches have been successfully carried out on the purification of shellfish for human consumption, particularly in the case of oysters and mussels. These shellfish, if obtained from accredited sources of supply under government supervision, can at the present time be guaranteed as free from pathogenic infection, and regular tests are made to ensure the safety of the shellfish put on the market.

Tinned fish.—This, like tinned meat, may give rise to poisoning from the contamination of the food by bacteria before canning. It is important to remember that tinned fish, even if wholesome at the time the tins are opened, is very liable to bacterial contamination. It should never be kept, but should be eaten on the day of opening.

Vegetables and fruit.—These may, if contaminated by bacteria of the type described, give rise to the disease. Since, however, the bacteria find vegetables an unsuitable medium for growth, outbreaks of food poisoning from vegetables are uncommon.

Milk.—Milk has on several occasions been the cause of outbreaks of food poisoning, and both Salmonella organisms and staphylococci have been found present in the affected milk. If milk is infected with the microbes, all that is necessary is a suitable temperature for their growth, and it speedily becomes a dangerous article of food. It is readily understood, therefore, that these cases are of much commoner occurrence in the warm weather of summer. Carriers of Salmonella organisms are a common cause of outbreaks due to milk or cream. Milk and cream may be contaminated with pathogenic organisms, and give rise to epidemics, *e.g.* typhoid and paratyphoid fever, from polluted water or from carriers handling the milk. In a similar manner outbreaks of tonsillitis and scarlet fever may result from carrier infections.

W. H. Willcox.
Donald Hunter.

Bacteriology.—Following work by Savage in this country, and by Jordan in America, bacterial food poisoning came to be regarded as synonymous with infection by food-borne Salmonella bacilli. This group of bacilli, like typhoid and dysentery bacilli fail to ferment lactose, but differ by fermenting glucose, mannite and dulcite with the formation of gas.

In the first decade of the century the best-known bacilli of this group were the paratyphoid and enteritidis bacilli, but in 1912 Bainbridge, in the Milroy Lectures, differentiated *Bact. enteritidis aertrycke* from *Bact. paratyphosus* B, and established the fact that *Bact. aertrycke* was a much more important cause of acute epidemic food poisoning than *Bact. paratyphosus* B. By absorption methods of agglutination he showed that the two bacilli were separate entities, although their sugar reactions were identical. *Bact. aertrycke* was subsequently identified with *Bact. typhi-murium*, by which name it is now known. The result of Bainbridge's work was to establish the fact that with few exceptions epidemic food poisoning is caused by *Bact. typhi-murium* or *Bact. enteritidis* (B. Gaertner). Thus Scott, during the years 1923–34, investigated 186 outbreaks of food poisoning in this country. No less than

110 of these were caused by *Bact. typhi-murium*, while 19 were due to *Bact. enteritidis*, 16 to *Bact. thompson*, 13 to *Bact. newport*, and 8 to *Bact. cholera-suis* and its variety *Bact. cholera-suis var. kunzendorf*.

Many of these bacilli are well known as causing infections in animals, and though the consumption of meat from "emergency slaughtered" animals is rare in this country, in Germany, on the other hand, it is common, as is also the consumption of uncooked or partially-cooked meat. Thus Meyer, in 1929, reporting on the incidence of Salmonella food poisoning in Germany following the consumption of meat and meat products during the years 1923–28, alludes to 493 outbreaks, with 14,567 cases and 133 deaths; while Savage and White, from January 1921 to October 1923, reported 86 outbreaks in this country, with 2300 cases and 24 deaths.

Failure to recover bacilli of the Salmonella group from some cases of bacterial food-poisoning led Savage to suggest that some cases were caused by the ingestion of the products of previously existing bacilli, which had been killed in the preparatory processes, usually canning. This involved the existence of specific exotoxins in connection with the various bacilli involved, which, be it noted, were not limited to the Salmonella group. The symptoms of this "toxin" type of food poisoning tended to come on with less delay than was observed with infections with members of the Salmonella group, and the vehicle tended to be of the canned type, whereas the "infective" type was usually associated with more recently prepared foods. Moreover, in 1930 Dack and Jordan announced the discovery of cases of staphylococcal food poisoning. Since then many cases have been reported. Most of these have followed the consumption of milk products, though some have been traced to gravy, canned meat, pressed beef or fish. No one type of staphylococcus has been involved; indeed, very few strains of staphylococci appear to have this property of toxin formation. That a preformed toxin is involved seems certain, in that the opportunity for the multiplication of the staphylococci before the consumption of the food is an antecedent necessity. The toxin is resistant to heat to such an extent that it is not completely destroyed by boiling for 30 minutes. It has very little effect on ordinary laboratory animals. Other cases of this type of "Toxin" food poisoning have occurred, due to such organisms as coliform bacilli in milk, and streptococci in fish, etc. Scott has suggested that about one-third of the reported outbreaks of food poisoning in this country are the result of staphylococcal intoxication, and Topley and Wilson suggest that another third may be due to other species of bacteria.

The general method of investigating outbreaks of food poisoning is described in a memorandum by the Ministry of Health (1935).

Chronic food poisoning differs from the epidemic type in that it is met with in individuals with no relationship, or no recent relationship, to epidemics of food poisoning. It is usually diagnosed in the laboratory, though a history of recurrent attacks of diarrhœa, or even of gastro-enteritis, perhaps over a number of years, and possibly dating from a typhoid-like illness may suggest to the clinician the presence of a member of the food-poisoning group of bacilli. Such infections are not infrequently met with in cases of colitis or "intestinal toxæmia," or may be disclosed in the routine examination of the intestinal contents, in which no intestinal symptoms exist. Such examination may disclose the presence of non-lactose-fermenting bacilli, and

exploitation thereof by way of vaccine therapy may strengthen the hypothetical connection between the infection and clinical condition.

The variety of bacilli thus found in connection with chronic food poisoning is much larger than is the case with acute epidemic food poisoning, which, as shown above, tends to be confined to few types, viz. *Bact. typhi-murium* and *Bact. enteritidis*. A condensed table of the chief sugar reactions and characteristics of these non-lactose-fermenting bacilli follows:

	Lactose.	Glucose.	Mannite.	Dulcite.	Saccharose.	Indole.	Motility.	
Bact. typhosus . .	—	A	A	--	--	—	+	Described by Eberth in 1880. Cultivated by Saffrey in 1884.

(+) indicates formation of acid and gas in sugar tubes, or formation of indole, or active motility, respectively.

(—) indicates the converse, respectively.

(A) indicates formation of acid, without gas, respectively.

The group of Salmonella bacteria typified by *B. paratyphosus* A and B, *B. typhi-murium* and *B. gaertner* constitute upwards of sixty named varieties of bacilli. Their ultimate classification depends upon the composition of their antigens—flagellar and somatic—indeed, their antigenic analysis.

The ultimate classification of any particular intestinal bacillus must rest upon specific serum agglutinations, antigen analyses and absorption tests. Such tests have differentiated from 60 to 70 varieties of bacilli in the "Salmonella" group alone.

The foregoing bacilli are the common abnormal bacteria found in epidemic and chronic food poisoning. The list is not to be taken as in any way exhaustive. There are, for instance, bacilli giving the sugar reactions of the paratyphoids which do not agglutinate with the specific sera of the members noted above, nor yet with a mixed Salmonella serum as issued by the Oxford laboratory, and yet which are controlled by an autogenous vaccine. There is more than one variety of Morgan's bacillus, and Castellani has described a *Bact. pseudo-asiaticus*, which ferments dulcite, specimens of which are occasionally found in the human stool in this country. Again there appears to be a group of "late-lactose-fermenting" bacilli, which give the reactions of the Salmonella group, and after a lapse of perhaps 48 hours lactose is fermented. Finally, there is a group which gives acid fermentation of glucose, mannite and dulcite, without gas, many of which are promptly controlled by the use of an autogenous vaccine.

JOHN MATTHEWS.

Pathology.—The *post-mortem signs* are those of an acute gastro-enteritis, with evidence of a general bacterial infection or toxæmia. When diarrhœa has been very severe, the tissues of the body may be shrunken from drainage of fluid. Rigor mortis sets in early. The stomach may show some redness from congestion, and, especially where vomiting has been severe, there may be small submucous hæmorrhages. Much mucus is generally present, but the stomach contents are free from blood. The inflammatory signs in the small intestines are usually more marked than in the stomach, which is an important distinction from chemical irritant poisoning, such as that caused by arsenic. The mucous membrane is swollen and congested, and the lymphoid follicles and Peyer's patches often show marked swelling and congestion. The signs are often more marked in the ileum than in the upper part of the small intestine. The mucous membrane of the large intestine may be swollen and congested, and the lymphoid follicles much enlarged. The contents are liquid and may contain much mucus. Small submucous hæmorrhages may occur in any part of the intestinal tract. The spleen is congested and soft, and in cases where infection with living bacteria has occurred, it may be enlarged. The liver and kidneys may show cloudy swelling or fatty degenerative changes. It is important to remember that in fatal cases of food poisoning the macroscopic morbid changes found post mortem may be very slight. Cultures made from the blood in the heart, from the spleen, and from the intestinal contents may reveal the presence of food-poisoning organisms.

Symptoms.—*Latent period.*—The period which elapses between partaking of the contaminated food and the onset of symptoms may vary from a few hours to 3 or 4 days. Usually, however, the latent period is short, from 2 to

6 hours being common. The greater the amount of preformed bacterial toxins in the food, the earlier will be the appearance of symptoms. The latent period is influenced by other conditions. Thus, if the poisonous food is taken on an empty stomach, the symptoms will come earlier. Again, if the infected food is taken alone, the symptoms will occur earlier than if it is taken with a considerable amount of other wholesome food.

The symptoms are of sudden onset, and in some cases a rigor may usher in the attack. The symptoms are usually those of gastro-enteritis, namely, furred tongue, severe abdominal pain and a rise of temperature, and often vomiting and purging. The stools are liquid and very offensive, and sometimes contain mucus and blood. In severe cases there may be cramps in the calves of the legs, and collapse with heart weakness, and the patient may become cold and blue owing to the feeble circulation consequent on a state of extreme collapse. In some cases rashes appear of the type of "erythema," and in severe cases "purpura." Often the severe cases present the symptoms of bacterial infection of the blood (septicæmia) and such complications as pneumonia or toxic jaundice are then likely to occur. In some attacks of food poisoning, especially those due to contaminated fish, the toxins appear to act especially on the blood vessels, producing rashes with considerable swelling of the skin (erythema and urticaria), which are associated with fever and a furred tongue, though there may be but little or no diarrhœa and vomiting. In these cases, idiosyncrasy or allergy may play an important part.

Diagnosis.—The diagnosis is usually clear, from the sudden onset of typical symptoms a short period after taking contaminated food. A specimen of the stool should be taken for bacteriological examination in order to determine the presence of organisms of the Salmonella group, etc. A sample of blood should be taken for agglutination tests with organisms of the food-poisoning group, and the blood agglutination tests should be repeated after an interval of a few days, when a rise in the agglutination titre would be expected. It cannot be too strongly emphasised that the symptoms of bacterial food poisoning are almost identical with those of poisoning by arsenic or antimony or other chemical irritant poison. An analysis of the vomit, fæces and urine for arsenic and irritant chemical poisons at once renders the diagnosis clear.

Course and Prognosis.—In mild cases, the symptoms clear up in a few days and the patient is completely restored to health. Where there is an actual infection with living pathogenic organisms the illness may run a course similar to that of typhoid fever. Severe cases may present symptoms so acute as to resemble true cholera, and in these the prognosis is grave.

Complications and Sequelæ.—An attack of bacterial food poisoning may be complicated by the development of a specific disease, such as enteric or paratyphoid fever, owing to the living organisms of this disease being also present in the contaminated food. After an attack of bacterial food poisoning there is sometimes left a latent bacterial intestinal infection so that the patient, in addition to being a "carrier" of disease, is liable to recurring attacks of enteritis from slight causes.

Treatment.—PROPHYLACTIC.—The importance of this has been already indicated above. The greatest care should be taken in the avoidance of articles of food likely to be contaminated, and the efficient cooking of food

whereby any living bacteria present are destroyed is a great safeguard. After cooking, rigid care should be taken in the storage of food to prevent contamination.

General treatment.—Rest in bed is essential. The diet should consist of liquids, such as water, albumin water, dextrose 5 per cent. solution in normal saline, chicken broth or whey. *Milk* is often best avoided ; peptonised milk or citrated milk (2 grains of sodium citrate to the ounce of milk) diluted with an equal quantity of water may be given. The feeds should consist of 3 or 4 ounces of liquid every 2 hours, and to these 1 or 2 teaspoonfuls of brandy may be added with advantage. As the symptoms improve, the dietary is gradually increased. Hot applications to the abdomen are advisable. Where there is much pain and diarrhœa without collapse, the hypodermic injection of morphine is advisable. This may be given with advantage with atropine, *e.g.* morphine hydrochlor. gr. $\frac{1}{6}$, atropine sulph. gr. $\frac{1}{100}$. Colon irrigations with 2 pints of normal saline are of value in cases with diarrhœa and slight collapse. In cases with choleraic symptoms and marked collapse, subcutaneous or intravenous injections of normal or hypertonic saline should be given. (See Article on Treatment of Cholera, p. 120.) A mixture of bismuth and soda with hydrocyanic acid is of value in relieving the gastric irritation, and to control the diarrhœa bismuth salicylate in 10 or 15 grain doses is useful.

The treatment of a case of food poisoning should be accompanied by periodical bacteriological investigations of the stools, and a case cannot be regarded as cured until three successive bacteriological examinations made at intervals of 2 or 3 days have shown freedom from infection with the pathogenic organisms of the disease.

W. H. Willcox.

BOTULISM

Synonyms.—Sausage poisoning, Allantiasis.

Definition.—A rare, but very fatal form of poisoning due to the effect on the nervous system of the toxins of the *Bacillus botulinus*. Botulism belongs to the food-poisoning class of disease, but differs from the old conception of ptomaine poisoning, in which the actual poison was supposed to be altered food product, on the one hand, and from the bacterial food poisonings, in which an actual infection is transmitted, on the other hand. Ptomaine poisoning has now only historic interest, and the bacterial food poisonings fall into the group of infections known as enterica, in which a period of incubation is involved, and more or less symptoms of gastro-enteritis occur. Botulism depends upon the ingestion of a certain minute quantity of preformed toxin, and in no way upon the introduction of the bacillus or spores thereof.

Bacteriology.—*B. botulinus* is a large gram-positive bacillus, 4–9 μ long by 0·9 1·2 μ broad. It stains well with ordinary dyes, but tends to lose Gram's stain if care be not taken. It possesses flagella, and is slightly motile. It forms terminal or sub-terminal spores, especially, in the case of most strains, at a temperature between 20° and 25° C. Likewise the optimum temperature of growth for most strains is between 20° and 30°. The bacillus is a strict anaerobe, and will only grow in slightly alkaline or neutral media.

In deep stab culture growth occurs as a thin whitish streak, not reaching to the surface; later the medium is cracked by the abundant formation of gas. With strict anaerobiosis the organism grows well on the ordinary media. Gelatine is liquefied. There are two types, A and B. They are readily separated by the fact that chickens are susceptible to type A only. Three different strains are named. They are the Boise (type A), the Nevin (type B), and the Memphis (type A). Type A is more common on the Pacific Coast of America, while type B is more common in the Eastern States, and in Europe. The strains differ in their behaviour to heat. Most strains are killed by boiling, but the Boise strain can survive boiling for an hour, and consequently steam pressures are necessary to sterilise adequately food products contaminated therewith. The toxins of the various strains all seem to be destroyed by temperatures slightly less than 80° C., the Boise strain toxin being destroyed by 10 minutes at 73° C. The toxicity of the toxin can be so high that 0·0001 c.c. of the filtrate of a culture grown at 35° C. proved lethal to a guinea-pig of 350 g. The Boise strain also differs from the others in that it grows best at or about body temperature, and has a characteristic odour.

Symptoms.—There being no incubation period, there are no symptoms prior to the onset of the dizziness and diplopia that constitute the first signs of the involvement of the cranial nerves. Occasionally there are some abdominal pains, accompanied by vomiting, and there is some weight in the suggestion that the vomiting denotes an unusually heavy dose of toxin, for vomiting usually presages a fatal termination. Other cranial nerves are gradually affected, the larynx becomes involved and speech may be lost, and later respiration and the heart's action become affected, by reason of the involvement of the spinal accessory and vagus. Consciousness is not lost. Obstinate constipation is the rule, in sharp contrast to the diarrhœa usually associated with enterica. Botulism differs from encephalitis lethargica in that there is an entire absence of the somnolent state characteristic of the latter condition, while the absence of fever differentiates it from anterior poliomyelitis.

Prognosis.—This is very grave, the mortality being more than 50 per cent. In some outbreaks, for instance that of Loch Maree, every case proved fatal. Death may take place in 36 hours, or may be delayed for a week.

Treatment.—Antitoxin given experimentally with toxin prevents the fatal effect of the latter. In practice, antitoxin treatment will only be available for use in the later or less severe cases of an outbreak. Measures to promote elimination of toxin are called for, but are handicapped by the obstinate constipation. Alcohol appears to have a distinct effect in "denaturing" the toxin, and may, therefore, be given freely, partly for this effect and partly for stimulation. Strychnine should also be given. Ether anæsthesia is said to delay fixation of toxin by the tissues, and if so it might be usefully employed while antitoxin was being procured. Some relief from the mental distress due to the absence of unconsciousness would also accrue.

JOHN MATTHEWS.

SECTION VI

DISEASES OF METABOLISM

BASAL METABOLISM

By basal metabolism is meant the metabolism of an individual when he is lying down in as complete a condition of rest as possible, and has taken no food for 14 hours—the post-absorptive state.

Basal metabolism is increased by the intake of food, and the amount and nature of the food determines the amount of its increase. Exercise also increases metabolism, and considerably so. In order to obtain an accurate estimate, certain precautions are therefore necessary. It is customary to prescribe a light evening meal some 14 hours before the test, and to make the subject lie down, with the muscles in complete relaxation, for half an hour. The actual estimation may be performed in two ways, namely, by the direct method and by the indirect method, the latter being easier but not so accurate. In the direct method, the air which is breathed out under the standard conditions is collected in a Douglas bag for 10 minutes and the total volume measured. The amounts of carbon dioxide and oxygen present are estimated by means of a Haldane gas analysis apparatus. By this means the Respiratory Quotient (R.Q.), *i.e.* the ratio of the volume of carbon dioxide given out to the volume of oxygen taken in, and the amount of oxygen used may be determined with great accuracy. In the indirect method, the subject breathes oxygen which is in a closed system for 10 minutes. The carbon dioxide formed is absorbed with soda lime, and the oxygen which has been used is calculated from the amount of gas which has disappeared from the system. The surface area of the body in square metres is then estimated from the weight and height of the patient by means of the nomograph (Fig. 7). The amount of oxygen which has been used by the patient is then expressed in terms of one square metre of body surface per minute. The next step may be done in one of two ways. (1) The amount of oxygen per square metre of body surface is compared with the amount of oxygen which an average subject of the same age and sex consumes (see Table I.). (2) The number of heat calories which the oxygen would give when burnt under standard conditions is ascertained from the tables of oxygen values, and this result is compared with the calories per square metre of body surface which an average subject of the same age and sex would consume (see Table II.). The final result in either method is expressed as plus or minus x per cent. as compared with the average values in the case of normal people.

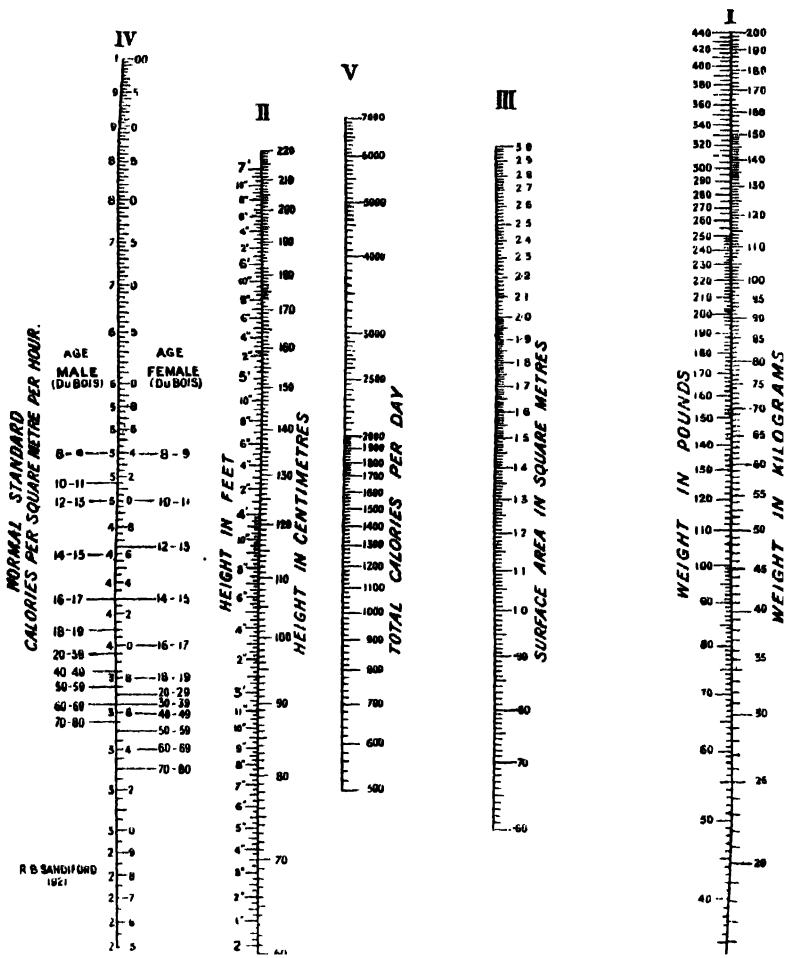

FIG 7.—BOOTHBY AND SANDIFORD'S NOMOGRAPH.

The weight in pounds or kilogrammes is shown on Scale I. The height in inches and centimetres is shown on Scale II. The surface area in square metres is shown on Scale III. The normal standard calories per square metre of body surface per hour are shown on Scale IV. The total calories per diem are shown on Scale V.

Directions.—Keep the chart flat. Use a flexible ruler with a straight edge, or a strip of stiff paper, such as a postcard. (A) Locate the position of the weight and height on Scales I. and II. respectively. Apply the straight edge of the ruler, and note where it cuts Scale III. Read the figure on Scale III., which will give the surface area of the body in square metres. (B) Locate the surface area on Scale III., and the normal standard calories per square metre per hour for the age and sex of the subject on Scale IV. Apply the straight edge of the ruler, and see where it cuts Scale V. Read this figure, which gives the total basal calories per 24 hours.

Large scale nomographs may be obtained from W. B Saunders Co., West Washington Square, Philadelphia, U.S.A., or from H. N. Elmer, 1641 Monadnock Buildings, Chicago, U.S.A.

It is accepted that the subject is normal if the figure lies within the limits of plus or minus 10 per cent. Important variations occur when the thyroid is affected. If the gland is atrophied or absent (myxœdema), the basal rate may be as low as minus 40 per cent.; while if it is overactive (exophthalmic goitre), the basal rate may be very high, varying from plus 15 to 20 per cent. to 100 per cent. or even more. In starvation and severe undernutrition, the basal rate will be below minus 10 per cent.

ACIDÆMIA, ALKALÆMIA, AND ALLIED CONDITIONS

Definitions.—*Acidæmia* signifies that there is an increase in the H-ion concentration of the blood. This may be due to an increase in the amount of CO_2 in the blood, or to an increase in the fixed acids of the blood. In the latter case, the acid unites with the bases and lowers the amount of CO_2 which can be carried in the blood. The name *acidosis* has been applied to this latter condition, but it has given rise to so much confusion that it is better to abandon the name altogether, and to speak of a decrease in the alkali reserve of the blood. *Alkalæmia* signifies that there is a decrease in the H-ion concentration of the blood. The name *alkalosis* has been used to describe the conditions in which there is an increase in the alkali reserve of the blood, but, for the same reason as for acidosis, it would be better to drop the name altogether, and to speak of an increase in the alkali reserve.

Physiology.—The reaction of a fluid is best expressed in terms of the concentration of the H ions. It is known that the H and OH ions react in accordance with the equation $(H)\times(OH)=(H_2O)$, and that the equilibrium reached obeys the law of mass action. This is expressed as follows: $\frac{(H)\times(OH)}{(H_2O)}=K$. The brackets signify concentrations and K is a constant, which is dependent on the temperature. Since the mass of the water is enormously greater than the mass of (H) and (OH) ions, (H_2O) may be regarded as a constant, and the equation may be written in a simpler form $(H)\times(OH)=K$. The constant K is called the dissociation constant of

water, and at 15° C. has the value of $10^{-14.14}$. If a solution is neutral, the concentration of H and OH ions will be equal, *i.e.* $(H) = (OH) = 10^{-7.07}$, since $(H) \times (OH) = 10^{-14.14}$. An acid solution has a greater concentration of H ions than OH ions, and it follows from the equation that an increase in the concentration of the H ions results in a decrease in OH ions, since K is a constant. It is inconvenient to express (H) as a negative and fractional power of 10, and Sörensen has introduced a notation which avoids this difficulty. Since $(H) = 10^{-7.07}$, −7·07 is, by the definition of the term logarithm, the log. of the H-ion concentration of water. Sörensen disregarded the negative sign and called the numeral 7·07 the *p*H value of water. It follows from this that as the *p*H value of a fluid increases, the H-ion concentration and, therefore, the acidity diminishes, because a large negative number is actually smaller than a small negative number. If a fluid has *p* H = 7·07 it is neutral, like water; if it has *p*H = 1 it has the acidity of decinormal hydrochloric acid; while if *p*H = 13·2 it has the alkalinity of decinormal caustic soda. Normal blood has a *p*H which is slightly alkaline, and lies between 7·34 and 7·47 by the Hydrogen Electrode Method and 7·64 and 7·72 by the Indicator Method. The figures for the Hydrogen Electrode Method will be used in this article.

It is very easy to change the reaction of a fluid like water, which only contains H and OH ions. Blood, however, is a very complex fluid, since it contains salts of weak acids, such as the acid and alkaline phosphates, and sodium bicarbonate, which, together with the hæmoglobin and proteins, act as "buffers" and prevent the reaction of the blood being easily changed. Further, other regulating mechanisms are at work, since urea can be split up into carbon dioxide and ammonia; the former can be excreted by the lungs, while the latter can be used to neutralise an acid. The kidney can excrete acid or alkaline salts which may be in excess, and thus help to keep the reaction of the blood constant. Much attention has been paid to the regulation of the blood by means of the sodium bicarbonate and carbon dioxide. In this process, the respiratory centre plays a very important rôle, since, if it is damaged in disease or by drugs, such as morphine, the regulating mechanism is upset. When a fluid contains only weak acids and their salts, the H-ion concentration varies according to the equation $(H) = \frac{(H_2CO_3)}{BHCO_3)} \times K$, when K is a constant, and the brackets signify concentrations. If there is an increase in the H-ions of the blood, there must be an increase in the size of the fraction $\frac{(H_2CO_3)}{(NaHCO_3)}$, since the value of K does not alter. The increase can be made in two ways, namely, either by decreasing the amount of $NaHCO_3$, or by increasing the H_2CO_3. If, on the other hand, the H-ion concentratiom is decreased, K can be kept constant, either by increasing the amount of $NaHCO_3$, or by decreasing the H_2CO_3. The amount of $NaHCO_3$ present in the blood is termed the alkali reserve. This is estimated by measuring the CO_2 present in the blood or plasma which has been exposed to CO_2 at a pressure of 40 mm. of Hg. (Van Slyke's method). The figure for normal blood lies between 40 and 55 vols. per 100 c.c., while that for plasma, which is the one usually estimated, is 55–70 vols. per 100 c.c. of blood. The estimation of the CO_2 in the alveolar air is also of assistance, since in health the CO_2 is present at the same tension in the blood and alveolar air. When the alkali reserve is reduced, there will

also be a decrease in the percentage of CO_2 in the alveolar air, from the usual figure of 5 per cent., which will keep the fraction $\frac{(H_2CO_3)}{(NaHCO_3)}$ constant, and so prevent any change in the *p*H. This will necessitate an increase in the volume of the respiration, as the same amount of CO_2 will be excreted under similar conditions of exercise and food. The increased depth of respiration is seen in the " air hunger " of diabetic coma.

Acidæmia.—This may be due to :

(1) A considerable increase in the H_2CO_3 of the blood together with a smaller increase in the alkali reserve. This occurs in morphine poisoning, since the respiratory centre is depressed and thus rendered insensitive to a small concentration of H_2CO_3.

(2) An increase in the H_2CO_3 of the blood, with little or no change in the alkali reserve. This occurs in emphysema, bronchitis, asthma and other causes of bronchial obstruction, in which there is difficulty in getting rid of the CO_2 from the blood.

(3) A decrease in the alkali reserve, with little or no change in the H_2CO_3. This condition may be due to many causes. The simplest are the administration of acids and acid salts, such as calcium chloride and ammonium chloride. In uræmia the condition is the result of the inability of the kidney to excrete acid salts. In diabetic coma and in the carbohydrate starvation which is found in cyclic vomiting, pernicious vomiting of pregnancy, and the vomiting due to chloroform or ether anæsthesia, the resulting ketosis is responsible for the acidæmia. It is believed that the enolic group $\begin{vmatrix} COH \\ CH \end{vmatrix}$ of aceto-acetic acid stimulates the respiratory centre. Acidæmia of this type is also met with in gastro-enteritis. In all these conditions there is an increase in the depth of the respiration, most marked in diabetic coma (air hunger), but may be very striking in the other conditions. The *p*H of the blood may rise to 7·25 or 7·3, and the alkali reserve may fall to 30 or 25 vols. of CO_2 per 100 c.c. ; and the percentage of CO_2 in the alveolar air may be reduced to 2 or 1·5 per cent. If the vomiting is very severe and the ketosis slight the patient will develop an alkalosis.

Alkalæmia.—This is the opposite of acidæmia, and may be due to :

(1) A considerable increase in the alkali reserve, with little or no increase in the H_2CO_3 of the blood. This may be the result of the administration of large doses of alkali, as in the treatment of gastric ulcer. The symptoms in this case are loss of appetite, severe headache, irritability, restlessness and tetany. The condition may also arise if a patient suffers from severe vomiting, without ketosis, as in pyloric obstruction or high intestinal obstruction, and in young children with hypertrophic pyloric stenosis. In such the symptoms are due to the loss of the hydrochloric acid and sodium chloride present in the vomit, which outweighs the tendency towards acidæmia produced by the ketosis, and has most effect when, for some reason, ketosis has not occurred. In all these conditions the kidneys may fail to excrete urea and other substances, and the patient may die of uræmia, although the organs are not obviously diseased. The alkali reserve is high, and may be 80 or 90 vols. of CO_2 per 100 c.c. of blood, while the *p*H of the blood is less than 7·5.

(2) A decrease in the alkali reserve with a considerable decrease in the

H_2CO_3 of the blood occurs in people who live in high altitudes. They are often cyanosed because the blood is anoxæmic. If an individual ascends quickly, he will at first suffer from dyspnœa as well as cyanosis. The lack of oxygen causes deeper respiration, and more carbon dioxide is washed out of the blood. In the attempt to compensate for this change, the kidney excretes less acid and more ammonia, and the urine becomes alkaline. The loss of alkali causes a decrease in the alkali reserve, and at first suggests that an acidæmia exists, but the fall in the *p*H is conclusive proof that the loss of CO_2 is greater than that of alkali $\frac{(H_2CO_3)}{(BHCO_3)}$. As the patient becomes acclimatised, the *p*H gradually rises to normal, although the cyanosis still exists.

Diagnosis.—This can only be made with certainty by employing the more accurate methods for determining (1) the H-ion concentration of the blood (Hastings and Sendroy), (2) the alkali reserve of the blood (van Slyke), (3) the alveolar CO_2 (Haldane and Priestley, Hasselbach, Fridericia), (4) the reaction of the freshly passed urine, (5) the amount of accto-acetic acid and ammonia in the urine, and (6) the amount of sodium bicarbonate which is necessary to make the urine alkaline. (In health a dose of 5 g. is sufficient to make the urine alkaline for a short while.)

Prognosis.—This depends almost entirely on the nature of the disease causing the condition.

Treatment.—This should be directed to removing the cause of the condition. The treatment of the ketosis which occurs in diabetes is described on p. 427. In acidæmia, sodium bicarbonate, ʒi (4 g.) 4-hourly, should be given together with dextrose 1 oz. (25 g.) 4-hourly, with an abundance of water; in severe cases it is better to give 600 c.c. of a mixture of 2 per cent. sodium bicarbonate and 10 per cent. dextrose intravenously. The treatment should, if possible, be controlled by estimations of the alkali reserve. Small doses of insulin, 10 to 20 units, may be of assistance. The bowels should be kept well open.

In alkalæmia, all alkalis should be stopped and acid sodium phosphate, gr. 30 (2 g.) 4-hourly, should be prescribed, besides sugar and water, as in acidæmia; in severe cases it is better to give 600 c.c. of a mixture of 10 per cent. dextrose intravenously. Here also treatment should, if possible, be controlled by estimations of the alkali reserve.

DIABETES MELLITUS

Diabetes mellitus is a disease in which the metabolism of carbohydrates, together with that of proteins and fats, is disturbed. The obvious signs of this are the presence of sugar and acetone bodies in the urine.

Ætiology.—(*a*) Predisposing Causes.—Diabetes is more common among Jews than Gentiles, and in Frankfurt 31·5 per cent. of the cases were of Jewish descent. It is also very common in a mild form among the natives of India and Ceylon. Heredity undoubtedly plays some part, as many members of a family may be affected. This can partly be explained as being due to the same excesses of diet, especially when the disease develops late in life. But this cannot explain all the cases, especially those which occur among the

younger members of the family. The familial form is sometimes very mild, but may be very severe. Joslin obtained a history of heredity in 13 per cent. of his cases. The inheritance of diabetes is probably a recessive characteristic. On this hypothesis, if two diabetics marry 100 per cent. of the children should develop diabetes, but so far only 8 out of 32 children, or 25 per cent., have done so; if a diabetic marries someone whose near relations have diabetes, 40 per cent. of the children should develop the disease, but only 48 out of 475 children, or 10 per cent., have been affected; and if two people whose near relations have diabetes marry, 16 per cent. of the children should become diabetic, but only 98 out of 2309 children, or 2.4 per cent., have had the disease. The discrepancy between the anticipated and observed figures is due to the short period in which the patients have been observed, as many of them may develop the disease in old age. (White and Pincus.) Cases of diabetes in husband and wife occur occasionally, but this is probably due to similarity of living and not to contagion. The disease is more common among males than females. It is commoner between the ages of 40 and 60; these two decades contained 48 per cent. of Joslin's cases, while only 7 per cent. of the cases occurred between the ages of 20 and 40, and 4 per cent. were under 20.

(*b*) Exciting Causes.—The disease is often present among elderly people who (1) take an excess of carbohydrate foods and sugar, (2) are considerably overweight, (3) have a blood pressure which is considerably raised, and (4) are subject to great anxieties. But the exciting cause of the acute disease which is seen in young people is quite unknown.

Pathology.—The blood normally contains sugar, and the amount varies in health between 80 and 120 mg. per 100 c.c. The total amount of sugar in the blood of a man weighing 65 kilos, or 10 st. 3 lb., would be 4 to 6 g. assuming that the total volume of the blood is $\frac{1}{13}$th of the body-weight, *i.e.* 5000 c.c. The percentage amount of sugar in the blood remains fairly constant, so long as no food is eaten. A dose of 50 g. of dextrose will cause a rise in the blood sugar in the arterial blood, from 100 to 150 to 180 mg. per 100 c.c. The change may be evident in 10 minutes, and usually reaches its maximum in 30 minutes. The sugar returns to its original level in a variable time—60, 90, 120 minutes, depending on the individual (Fig. 8). The sugar in the venous blood, after a carbohydrate meal, is about 20 mg. less than that in the arterial blood. Provided that the blood sugar does not exceed 180 to 200 mg. per 100 c.c. in the arterial blood, no sugar is excreted in the urine; but this again is a variable factor, as some people pass sugar at a considerably lower level than 180 mg. per 100 c.c., whereas others do not although the blood sugar rises to 250 to 300 mg. per 100 c.c. A carbohydrate meal produces a similar effect, but the rise is usually slower and more sustained. Protein does not cause any rise in the blood sugar of healthy people, but it does so in diabetic patients.

Some of the sugar which is eaten is burnt at once as the respiratory quotient approaches 1 after the dose of sugar, but the greater part of it must be stored, either in the liver or muscles. A healthy adult can usually eat 100 to 200 g. of pure dextrose without causing any glycosuria, but the individual variations are great.

In the mild cases of diabetes the blood sugar when fasting may be within

normal limits, but a dose of 50 g. of dextrose will raise the blood sugar from 120 mg. per 100 c.c. to above 200 mg. per 100 c.c. The maximum height may be reached in 1, 2 or 3 hours, and then the blood sugar returns slowly to its original level (Fig. 9). Sugar is excreted in the urine all the time the blood sugar is above the threshold of the kidney for the individual, which may be 180 mg. or 200 mg. per 100 c.c. In the more severe cases the blood sugar is always above the threshold, and sugar is excreted throughout the day. In these cases there is a decrease in the power of burning sugar, and the respiratory quotient does not approach 1 after a meal, and may be below 0·8. When the carbohydrate metabolism is seriously upset, proteins also cause a rise in the blood sugar, as 58 per cent. of the protein molecule is burnt as sugar. The thirst of which the patient complains is due to the excretion of the sugar, as apparently this cannot be excreted without a good deal of water.

When the sugar cannot be burnt properly, the metabolism of fat is also upset, and the fatty acids, aceto-acetic acid, β-oxybutyric acid, and acetone, are excreted in the urine. These are incomplete products of fat metabolism, and cannot be burnt completely in the absence of a certain amount of sugar metabolism. The amount of acetone excreted in the urine is very small; the aceto-acetic acid forms about 30 per cent. and β-oxybutyric acid 70 per cent. of the total acetone bodies if these are present in large amounts. This condition is now called ketosis, instead of acidosis, as usually there is no change in the H-ion concentration of the blood.

The amount of carbon dioxide in the alveolar air is usually over 5 per cent. in healthy persons, but it is reduced when ketosis is present (Beddard, Pembrey & Spriggs, Poulton). It may fall below 3 per cent., but this does not mean that the patient will pass into coma at once, but only that the condition is serious. If it falls below 2 per cent., the patient is usually comatose and is unlikely to recover unless insulin is injected in adequate amounts. The poisonous substance is probably aceto-acetic acid, acting not as an acid, but through the enolic group $\begin{matrix}|\\ COH\\ \|\\ CH\\ |\end{matrix}$. This acts on the respiratory centre (Hurtley and Trevan). The alkali reserve of the blood plasma is much reduced in severe cases and may fall from the normal 55 to 70 vols. per cent. to below 20 vols. per cent.

The sugar metabolism is controlled by the internal secretion of four glands, namely, that of the islands of Langerhans, this being opposed by the suprarenal gland, the thyroid gland, and the posterior lobe of the pituitary gland.

The islands of Langerhans.—The relation of the pancreas to the metabolism of sugar has been recognised ever since von Mering and Minkowski, in 1889, showed that complete removal of the gland caused glycosúria and death of the animal. If, in a dog, the remnant be $\frac{1}{8}$th to $\frac{1}{9}$th of the whole gland, mild diabetes occurs; if less than $\frac{1}{9}$th, severe diabetes results (Allen). The pancreas is made up of two glands:—(1) the acinous portion, which secretes the pancreatic juice through the pancreatic duct. It has no action on the

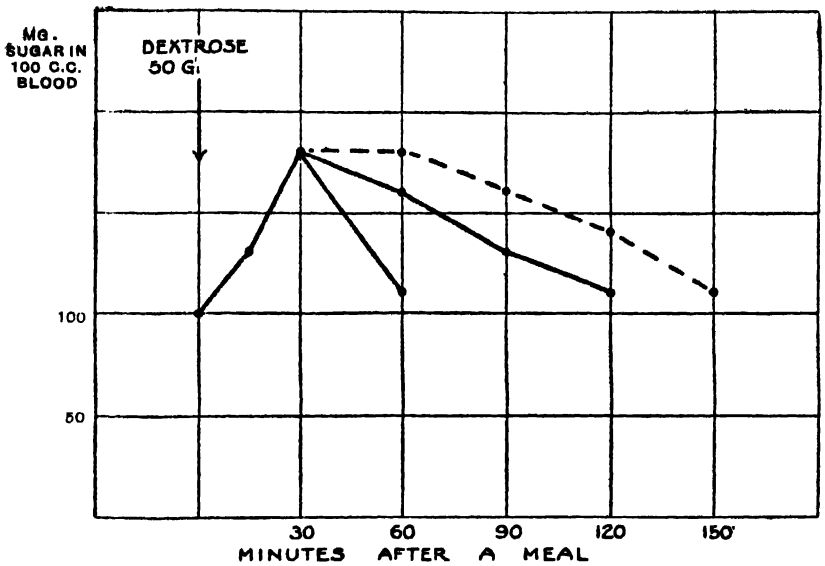

FIG. 8 —A normal curve.

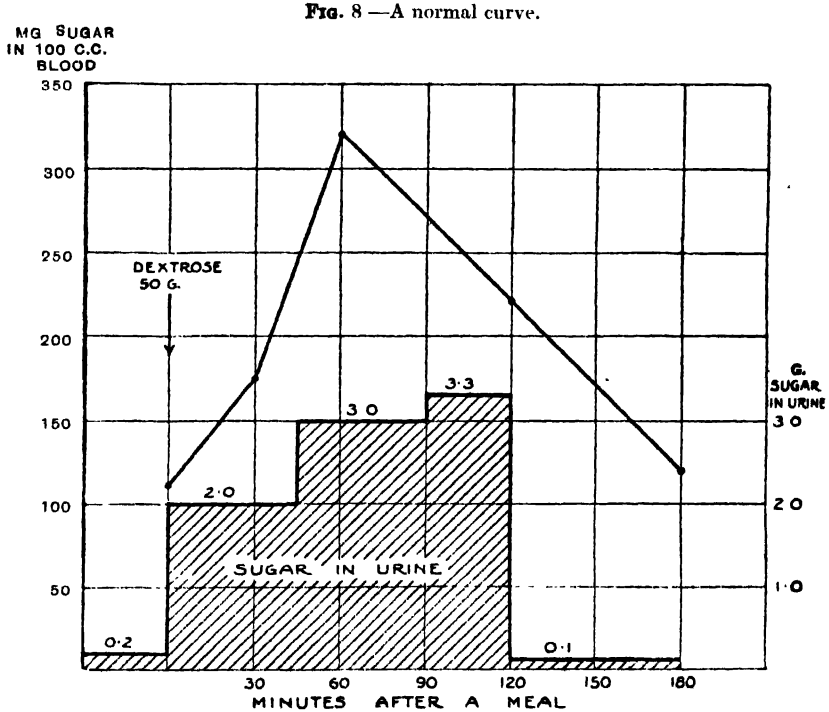

FIG. 9 —A mild diabetic curve.

sugar metabolism, since if it is entirely destroyed as a result of ligaturing the duct and replaced by fibrous tissue the sugar metabolism is quite unaffected so long as the islands of Langerhans are intact. (2) The islands, first described by Langerhans in 1869, are now recognised as definite entities, forming about $\frac{1}{100}$ part of the whole pancreas, and having an abundant blood supply. They contain three kinds of cells, called alpha, beta and gamma cells, which contain granules in their protoplasm as in the case of the gland cells of other organs. The alpha cells form about $\frac{1}{3}$rd, and the beta about $\frac{2}{3}$rds of the islands, while the gamma cells are few in number. The granules in the alpha cells stain differently from those in the beta and gamma cells, and these again stain differently from those in the acinous portion. Hence, if the tissues are fresh, the three kinds of cells in the islands can easily be distinguished from each other. When the surviving islands of a partially depancreatised dog are overworked by excessive sugar or carbohydrate feeding, only the beta cells are affected. The granules gradually disappear and a vacuole appears (hydrops of the cell). This process may continue until the cell finally consists of a large vacuole, with the nucleus flattened against one side, whilst all the granules have disappeared. Finally the cell breaks up and disappears. If the process is continued long enough the island will consist of alpha and gamma cells alone, and will be much smaller than usual. These experiments prove that it is the beta cells which control the sugar metabolism. The action of the alpha and gamma cells is unknown. The internal secretion of the beta cells had never been isolated until, in 1922, Banting, working with Best, succeeded in preparing an extract which had the power of lowering the blood sugar of a depancreatised dog, and of prolonging its life considerably. At first it was necessary to destroy the acinous portion of the pancreas by ligaturing the duct thirteen weeks before the extract was made, but now the extract is made from the fresh gland.

Properties of insulin.—The extract of the islands of Langerhans is called insulin. It has been prepared in crystalline form, and 1 mg. contains about 25 units. Its constitution is not known, but the molecule must be very complex since it contains 23–24 tyrosine groups as well as some sulphur atoms. It has considerable capacity for binding acids, for it forms salts with hydrochloric acid, and has a greater capacity for binding bases. It is destroyed by pepsin, trypsin and alkalis, and therefore cannot be absorbed from the alimentary canal. Insulin enables the blood sugar to be kept within normal limits, and the liver and muscle to contain plenty of glycogen, so that the respiratory quotient will be about 1·0 and the fat correctly burnt. If insufficient insulin is present, the blood sugar will be increased in amount; the liver and muscles will contain little glycogen, the respiratory quotient will be about 0·7; and the urine will contain sugar and also acetone bodies, as the fats cannot be correctly burnt under these conditions. If there is excess of insulin the blood sugar will be small in amount; the muscles will contain plenty of glycogen, but the liver will contain very little. The precise way in which insulin acts is not yet understood, as it has no action on dextrose outside the body.

The potency of insulin is estimated by its power to lower the blood sugar of a healthy fasting rabbit or mouse to a certain level. The amount of insulin which lowers the blood sugar of a healthy fasting rabbit weighing about 2 kg. to 45 mg. per 100 c.c. in 2 hours is termed 2 units, and this represents about 0·04 mg. of the pure product. All the insulin prepared in this country

has been carefully tested under the supervision of the Medical Research Council. It is dissolved in acid solution containing 0·5 per cent. of tricresol, and is of such a strength that 1 c.c. contains 20 units, 40 units (double strength), or 80 units (quadruple strength). It is put up in rubber-capped bottles, and does not deteriorate even in hot climates.

If too big a dose of insulin is given to a rabbit, the blood sugar will fall below 45 mg. per 100 c.c. and the animal may have convulsions and die. These symptoms can be relieved at once by the subcutaneous injection of 2 or 3 g. of sugar, unless the dose of insulin has been very large. Adrenaline, 1 in 1000, 0·3 c.c. (min. 5), or pituitary (posterior lobe) extract, 5 units

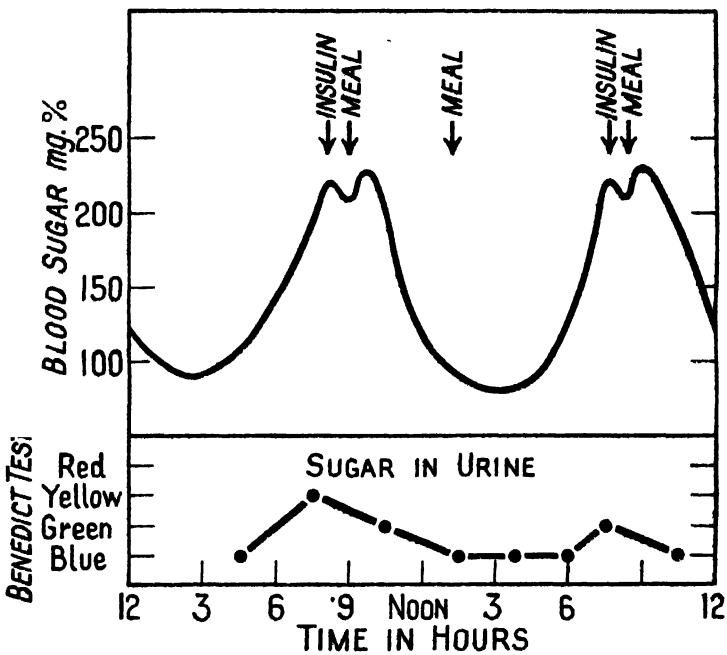

FIG. 10.—Figure showing the effect of a dose of insulin on the blood sugar and urine sugar of a diabetic patient.

(0·5 c.c.), will also relieve the symptoms at once. In human beings insulin acts in a similar manner, and if sufficient insulin is administered the blood sugar is always lowered. A dose of 5 to 10 units will lower the blood sugar of a healthy fasting adult of about 65 kilos to about 50 mg. per 100 c.c., but usually does not cause any symptoms of hypoglycæmia. Human beings, considering their much greater weight, are, therefore, much more sensitive to insulin than a rabbit.

When the blood sugar is raised, as in diabetes, the insulin causes a similar decrease in the blood sugar provided that a sufficient amount has been given. The extent to which the blood sugar is lowered varies in every patient and no definite law can be stated. The maximal decrease (Fig. 10) occurs about

nervous symptoms during life, there may be definite changes in the spinal cord, such as sclerosis of the posterior columns. There is no change in the sympathetic ganglia or in the pituitary gland. Atrophy or hypertrophy of the subcutaneous tissues may be seen at the site of the insulin injection.

LIPÆMIA.—In severe and advanced cases of diabetes the blood contains an excess of fat, either fatty acids or cholesterol. On separation of the corpuscles the plasma or serum has a pearly white appearance; this is always a sign of the severity of the disease, but patients have occasionally made fair recoveries of sugar tolerance. The retinal vessels in lipæmia are very striking objects. In the less severe cases, the arteries and veins have a salmon pink appearance throughout their course. In the more severe cases, the vessels at the periphery become creamy white in colour, although near the disk, they are still salmon pink. In the severe cases, the distinction between the arteries and veins is completely lost and the vessels resemble flat ribbons. The vision remains unaffected.

Symptoms.—The onset of the disease may be very acute and great thirst is complained of; the very day of onset of the thirst can sometimes be discovered. Some of these cases have died in coma, undiagnosed. Usually the onset of symptoms is insidious, with lassitude, loss of energy, or pruritus, thirst not being a prominent symptom. In the mild cases, especially among elderly people, the diagnosis is usually made either in the course of a routine examination, or by accident, *e.g.* because of the complaint of white spots on the clothes or boots. In severe cases, thirst is the most troublesome complaint, and this necessitates drinking a great deal of fluid and passing a great deal of urine. The pruritus also troubles the patients, especially as the usual situation for it is the penis in males and the vulva in females. Weakness is usually complained of, and sometimes a large appetite is a troublesome symptom. Constipation is usually present, and it dates from the onset of the thirst in the acute cases. The tongue does not present any changes in mild or treated cases, but in severe and untreated cases it is dry and red—the so-called "raw beef" tongue; this is only present when the patient is "desiccated," as a result of great polyuria. There is usually great loss of weight. In the severe cases, the volume of the urine may be 4, 6, 8 or even 10,000 c.c. per diem, but in the treated case it is usually less than 2000 c.c. The specific gravity of the urine in the untreated case may be 1040 or 1050, depending on the amount of sugar in the urine.

Complications.—(*a*) *Coma.*—Formerly this was a frequent termination of the disease, but now it should only be seen in: 1. The very acute and the undiagnosed cases. 2. The severe and untreated cases. 3. As a terminal event as a result of any acute infection. Out of 9 cases of coma, 7 showed definite signs of a severe disease, 1 became comatose 7 days after the onset of the thirst, and in 1 no cause for the coma was discovered (Graham). There are two main types, namely: (1) the hyperpnœa is well marked (air hunger), but the patient remains conscious until just before death; and (2) the hyperpnœa is not very obvious at first, but the patient becomes deeply unconscious a long time before death. More usually the patient shows a mixture of these two types. The blood pressure is low in both types, and the tension of the eyeball is very low. Constipation is always marked, and the contents of the intestines after death may be enormous.

(*b*) *Local infections*, such as boils and carbuncles, often occur, and the

latter is often a fatal complication. Perforating ulcers of the feet occur in long-standing cases with signs of peripheral neuritis. Pigmentation of the skin, especially on the back of the hands, occurs in bronzed diabetes.

(*c*) *Gangrene* of a limb, usually a leg, often occurs in elderly people. It is due to the associated arterial condition, and not primarily to the diabetic condition. Atheromatous changes in the arteries are present in many patients over the age of 40.

(*d*) *Pulmonary.*—Tuberculosis of the lungs is a common termination of the disease, and lobar and broncho-pneumonia are serious complications, as the patients pass rapidly into coma.

(*e*) *Renal.*—A trace of albumin is often present. Œdema may occur after two days of starvation, or after the administration of much sodium bicarbonate. Casts may be present in very large numbers in coma.

(*f*) *Nervous system.*—The knee-jerks may be lost early, but they may return if treatment is successful. Numbness and paræsthesia may be present, and the patients occasionally complain of a great deal of tingling pain in the legs and arms. Symptoms resembling those of tabes dorsalis and due to degeneration of the posterior columns may be present. The vibration sense is often diminished or even absent in the legs. The sensation of "hot and cold" may be lost, and this is associated with a lesion of the posterior nerve roots (radiculitis). The temperament of the patient often changes, partly as the result of dietetic deprivations.

(*g*) *Eyes.*—A retinitis, which can be distinguished from albuminuric retinitis, is apt to occur in elderly patients. If the blood sugar remains high the condition tends to spread and may cause marked loss of vision, but if the blood sugar is kept normal the retinitis either spreads slowly or may even retrogress. Cataract is met with in elderly patients, and in young patients with severe diabetes, which is difficult to keep under control. Operations for cataract may be safely performed if the diabetic condition is under good control. A retrobulbar neuritis may occur, especially in excessive tobacco-smoking. Lipæmia retinalis has already been described (p. 416).

(*h*) *Sexual functions.*—These may be undisturbed in the early stages of the disease, but the male may become impotent if the disease is badly treated. The female may become pregnant, but with care the pregnancy usually causes no untoward symptoms.

Diagnosis.—If the urine is tested the presence of a reducing substance is readily detected, but the nature of the reducing substance is less easily determined.

Fehling's solution is still commonly used, but the limitations of the test should be recognised. Equal quantities of solutions A and B should be freshly mixed, and equal quantities of urine and reagent boiled separately, mixed and not reboiled. If sugar is present in more than 0·5 per cent., the red precipitate comes at once, if in less than 0·5 per cent., it may not appear for one or more minutes. Fehling's solution is also reduced by glycuronic acid, uric acid, and creatinine. These substances are rarely present in sufficient amounts to reduce the copper solution, but when the urine is very concentrated they may cause a slight reduction.

Benedict's qualitative solution (copper sulphate, 17·3 g.; sodium citrate, 173 g.; anhydrous sodium carbonate, 100 g.; water to 1000 c.c.) is not reduced by these substances. It is much more reliable than Fehling's

solution and should replace it. Five or 3 c.c. of Benedict's solution and 10 or 6 drops of urine are boiled together for 2 minutes, or put in a boiling water bath for 5 minutes. If much sugar is present the precipitate develops on boiling, but small amounts may not cause a reduction before 2 minutes. The test will show the presence of sugar in a concentration of 0·08 per cent.

Benedict's solution is reduced by dextrose, lævulose, lactose, pentose and homogentisic acid (alkaptonuria), and special tests are necessary to distinguish these. Dextrose is dextro-rotatory, ferments with yeast, and yields crystals of glucosazone. Lævulose is lævo-rotatory, ferments with yeast, yields crystals of glucosazone, and gives Seliwanow's test. Lactose is dextro-rotatory, does not ferment with yeast, and yields a lactosazone with difficulty. Pentose is dextro-rotatory or optically inactive, is not fermented by yeast, and gives Bial's test. Homogentisic acid (alkaptonuria) reduces Fehling's and Benedict's solution to a deep brown colour; the urine blackens on standing, reduces an ammoniacal solution of silver nitrate to a black precipitate, and gives a momentary deep blue colour with the addition of a drop of very dilute ferric chloride. It does not ferment with yeast and is optically inactive.

If dextrose is present, disease of the other ductless glands and cerebral tumours should be excluded. The pigmentation of the skin of the body and of the backs of the hands, together with an enlarged liver (bronzed diabetes), should be looked for. Acute and chronic pancreatitis should be thought of before the diagnosis of a primary lesion of the islands of Langerhans is accepted. If small amounts of dextrose are present it is necessary to make a complete test of the sugar tolerance, with estimation of the blood sugar every quarter- or half-hour for 2 hours after a dose of sugar, in order to exclude the possibility of renal glycosuria (see p. 428).

Tests for Acetone Bodies.—*The ferric chloride test.*—Add the solution drop by drop until all the phosphates are precipitated. As soon as this occurs, a violet colour appears if aceto-acetic acid is present in the urine in any quantity. This is a test for aceto-acetic acid, which can be detected in watery solutions in a dilution of 1 in 100,000. In urine, however, the test is much less delicate, owing to the interference of the pigments in the urine. The presence of sodium salicylate in the urine may cause confusion, but the colour produced in this case is purple. The distinction can be made by boiling the urine with a little weak acetic acid, and repeating the test when the urine is cold. The aceto-acetic acid distils away, whereas the sodium salicylate is unaffected by the boiling. This possibility of confusion is avoided by always using Rothera's test.

Rothera's nitroprusside test.—Saturate the urine with ammonium sulphate crystals, add 2 c.c. of liquor ammoniæ fort., and then a few drops of a fresh solution of sodium nitroprusside. If a little aceto-acetic acid is present, the permanganate colour develops slowly; if a great deal, the colour develops instantaneously, and it is impossible to see through the mixture after 10 to 30 seconds. When the nitroprusside reaction is strongly positive, the urine should be diluted 1 in 5. If the colour still appears instantaneously and deepens rapidly there is a large amount of aceto-acetic acid present. Aceto-acetic acid can be detected in a dilution of 1 in 400,000, and acetone in a dilution of 1 in 10,000.

There is no colour test for β-oxybutyric acid, but it is always present when more than 2 g. of aceto-acetic acid are present.

Prognosis.—This depends, as in the case of other diseases, on the severity of the attack, the time which has elapsed between the onset of the disease and the commencement of treatment, the skill of the medical adviser, the care with which the patient follows the directions given, and the complications which occur. The attack is more likely to be severe and rapidly fatal in young people, but quite mild cases are often seen. In elderly people mild attacks are the rule, but severe attacks also occur. The prognosis had been much improved by the new dietetic treatment introduced in 1915. But although the prospects of life for several years were much better than they had been, the outlook remained a gloomy one for the patient with a severe form of the disease. The introduction of insulin has greatly improved the chances of life of all patients with any form of diabetes, but especially in the case of those with the severe forms. How much longer these patients will live it is impossible at present to say, but probably for many years, provided no complications occur. Out of 98 patients admitted to hospital before the end of 1923 and 1924, 55 were alive at the end of 1931, and 47 at the end of 1935. Insulin has completely altered the prognosis in the case of pregnancy. The risks usually attendant on the pregnancy and puerperium constitute the chief danger.

Treatment.—The general health of the patient should be treated. Any sources of infection, such as pyorrhœa, cholecystitis and boils, reduce the sugar tolerance considerably. The possibility of syphilis should also be inquired into, and, if necessary, treated.

Although the introduction of insulin has altered the prognosis, it has not altered the principles of treatment which have been in use for the last ten years. Great attention has always been paid to diet, but under the stimulus of insulin much more attention is being devoted to it. The principles which govern treatment are: (1) the blood sugar of the patient when fasting should be within the normal limits of 0·08 per 100 c.c. and 0·12 per 100 c.c., and should not rise above 0·19 per 100 c.c. at any time of the day. It follows from this that the urine should never contain any sugar. (2) The urine should not contain aceto-acetic acid. (3) The patient should understand that a large portion of the reserve power of the islands of Langerhans has been lost, and that additional insulin will probably be required whenever the patient has another illness.

Diet.—Although the principles of treatment have not altered, the details have changed very considerably. The chief alteration has been in the amount of carbohydrate and fat. It was believed that a diet was correctly balanced when the number of grammes of fat equalled the number of grammes of carbohydrate multiplied by two, plus half the number of grammes of protein. $F = 2\ C + \frac{1}{2}\ P$. It was soon recognised that this diet was not correctly balanced, since many patients, especially children, passed considerable amounts of acetone bodies in the urine. The amount of carbohydrate has, therefore, been increased and the fat decreased. It is too early to state what is the best balance, but the carbohydrate should not be less than the fat, and some workers believe that the carbohydrate should be twice or four times as much as the fat.

The treatment should be begun as soon as the diagnosis has been confirmed

solution and should replace it. Five or 3 c.c. of Benedict's solution and 10 or 6 drops of urine are boiled together for 2 minutes, or put in a boiling water bath for 5 minutes. If much sugar is present the precipitate develops on boiling, but small amounts may not cause a reduction before 2 minutes. The test will show the presence of sugar in a concentration of 0·08 per cent.

Benedict's solution is reduced by dextrose, lævulose, lactose, pentose and homogentisic acid (alkaptonuria), and special tests are necessary to distinguish these. Dextrose is dextro-rotatory, ferments with yeast, and yields crystals of glucosazone. Lævulose is lævo-rotatory, ferments with yeast, yields crystals of glucosazone, and gives Seliwanow's test. Lactose is dextro-rotatory, does not ferment with yeast, and yields a lactosazone with difficulty. Pentose is dextro-rotatory or optically inactive, is not fermented by yeast, and gives Bial's test. Homogentisic acid (alkaptonuria) reduces Fehling's and Benedict's solution to a deep brown colour; the urine blackens on standing, reduces an ammoniacal solution of silver nitrate to a black precipitate, and gives a momentary deep blue colour with the addition of a drop of very dilute ferric chloride. It does not ferment with yeast and is optically inactive.

If dextrose is present, disease of the other ductless glands and cerebral tumours should be excluded. The pigmentation of the skin of the body and of the backs of the hands, together with an enlarged liver (bronzed diabetes), should be looked for. Acute and chronic pancreatitis should be thought of before the diagnosis of a primary lesion of the islands of Langerhans is accepted. If small amounts of dextrose are present it is necessary to make a complete test of the sugar tolerance, with estimation of the blood sugar every quarter- or half-hour for 2 hours after a dose of sugar, in order to exclude the possibility of renal glycosuria (see p. 428).

Tests for Acetone Bodies.—*The ferric chloride test.*—Add the solution drop by drop until all the phosphates are precipitated. As soon as this occurs, a violet colour appears if aceto-acetic acid is present in the urine in any quantity. This is a test for aceto-acetic acid, which can be detected in watery solutions in a dilution of 1 in 100,000. In urine, however, the test is much less delicate, owing to the interference of the pigments in the urine. The presence of sodium salicylate in the urine may cause confusion, but the colour produced in this case is purple. The distinction can be made by boiling the urine with a little weak acetic acid, and repeating the test when the urine is cold. The aceto-acetic acid distils away, whereas the sodium salicylate is unaffected by the boiling. This possibility of confusion is avoided by always using Rothera's test.

Rothera's nitroprusside test.—Saturate the urine with ammonium sulphate crystals, add 2 c.c. of liquor ammoniæ fort., and then a few drops of a fresh solution of sodium nitroprusside. If a little aceto-acetic acid is present, the permanganate colour develops slowly; if a great deal, the colour develops instantaneously, and it is impossible to see through the mixture after 10 to 30 seconds. When the nitroprusside reaction is strongly positive, the urine should be diluted 1 in 5. If the colour still appears instantaneously and deepens rapidly there is a large amount of aceto-acetic acid present. Aceto-acetic acid can be detected in a dilution of 1 in 400,000, and acetone in a dilution of 1 in 10,000.

There is no colour test for β-oxybutyric acid, but it is always present when more than 2 g. of aceto-acetic acid are present.

Prognosis.—This depends, as in the case of other diseases, on the severity of the attack, the time which has elapsed between the onset of the disease and the commencement of treatment, the skill of the medical adviser, the care with which the patient follows the directions given, and the complications which occur. The attack is more likely to be severe and rapidly fatal in young people, but quite mild cases are often seen. In elderly people mild attacks are the rule, but severe attacks also occur. The prognosis had been much improved by the new dietetic treatment introduced in 1915. But although the prospects of life for several years were much better than they had been, the outlook remained a gloomy one for the patient with a severe form of the disease. The introduction of insulin has greatly improved the chances of life of all patients with any form of diabetes, but especially in the case of those with the severe forms. How much longer these patients will live it is impossible at present to say, but probably for many years, provided no complications occur. Out of 98 patients admitted to hospital before the end of 1923 and 1924, 55 were alive at the end of 1931, and 47 at the end of 1935. Insulin has completely altered the prognosis in the case of pregnancy. The risks usually attendant on the pregnancy and puerperium constitute the chief danger.

Treatment.—The general health of the patient should be treated. Any sources of infection, such as pyorrhœa, cholecystitis and boils, reduce the sugar tolerance considerably. The possibility of syphilis should also be inquired into, and, if necessary, treated.

Although the introduction of insulin has altered the prognosis, it has not altered the principles of treatment which have been in use for the last ten years. Great attention has always been paid to diet, but under the stimulus of insulin much more attention is being devoted to it. The principles which govern treatment are: (1) the blood sugar of the patient when fasting should be within the normal limits of 0·08 per 100 c.c. and 0·12 per 100 c.c., and should not rise above 0·19 per 100 c.c. at any time of the day. It follows from this that the urine should never contain any sugar. (2) The urine should not contain aceto-acetic acid. (3) The patient should understand that a large portion of the reserve power of the islands of Langerhans has been lost, and that additional insulin will probably be required whenever the patient has another illness.

Diet.—Although the principles of treatment have not altered, the details have changed very considerably. The chief alteration has been in the amount of carbohydrate and fat. It was believed that a diet was correctly balanced when the number of grammes of fat equalled the number of grammes of carbohydrate multiplied by two, plus half the number of grammes of protein. $F = 2\ C + \frac{1}{2}\ P$. It was soon recognised that this diet was not correctly balanced, since many patients, especially children, passed considerable amounts of acetone bodies in the urine. The amount of carbohydrate has, therefore, been increased and the fat decreased. It is too early to state what is the best balance, but the carbohydrate should not be less than the fat, and some workers believe that the carbohydrate should be twice or four times as much as the fat.

The treatment should be begun as soon as the diagnosis has been confirmed

by the estimation of the blood sugar. In the mild type of case which occurs among elderly people, moderate restrictions of the carbohydrate may be sufficient to prevent glycosuria, but in the great majority of cases this is quite inadequate. The removal of carbohydrates from the diet without reduction of the fat and protein of the diet is a dangerous practice, and has in the past precipitated the onset of coma. Before the discovery of insulin, it was customary to starve the patient until no sugar was excreted in the urine (Allen). Such prolonged fasts are no longer used, and provided that the patient is willing to have insulin, any form of fasting is unnecessary. So many patients have a prejudice against insulin that an attempt is usually made to render the blood sugar normal by dietetic treatment. In the mild case, a fast of one day is sufficient to lower the blood sugar to normal, and always makes the patient much more amenable to the drastic change in the diet. If it is desirable to avoid a period of fasting, the patient may be given at once a diet which is just sufficient to satisfy the basal needs of the body. Whichever plan is adopted, it is of assistance to know the calories required, as the amount of food must be varied according to the size, age, and sex of the patient. An approximate figure can be obtained by multiplying the patient's weight by 11·3. Nearly always there will be an error by this method, but it will not be great. To obtain an accurate result, the following calculations are necessary. The patient's weight and height are marked on the Boothby and Sandiford Nomograph (p. 404). The figure for the surface area of the body is noted. Example: Height, 63 inches; weight, 132 lb.; surface area, 1·62 square metres. The calories required for each square metre of body surface are found in the Aub-Du Bois table below, which, in the case of a man aged 40, are found to be 1497.

AUB-DU BOIS TABLE.—Caloric Requirement per Square Metre of Body Surface.

Age (years).	Calories per day.		Age (years).	Calories per day.	
	M.	F.		M.	F.
10–12	1236	1200	20–30	948	888
12–14	1200	1116	30–40	948	876
14–16	1104	1032	40–50	924	864
16–18	1032	960	50–60	900	840
18–20	984	912	60–70	876	816

M. = males. F. = females.

Calculate requirement in children according to weight. Up to—

22 lb.	27·5 cals. per lb.
22–33 lb.	25·0 " "
33–44 lb.	23·0 " "

The number of calories is divided between the carbohydrate, protein and fat in the following way: for an adult, half a gramme of protein per one pound of body weight is allowed. In the sample case the allowance is 66 g. This figure multiplied by 4·1 (the caloric value of protein) gives 270 calories, and leaves 1227 for division between the carbohydrate and fat. In order to prevent any ketosis, the balance between these two must

be carefully struck. The carbohydrate should not be less than 70 g. This figure multiplied by 4·1 (the caloric value of carbohydrate) gives 287 calories; 1220 minus 287 leaves 933 calories for the fat, and this figure divided by 9·3 (caloric value of fat) gives 100 g. for the fat. The diet is then prescribed as: carbohydrate (C), 70 g.; protein (P), 66 g.; fat (F), 101 g.; calories (Cals.), 1497. The total amount of calories is divided into four meals, of approximately the following amounts: Breakfast: C, 20 g.; P, 20 g.; F, 30 g.; Cals., 443. Midday, C, 20 g.; P. 20 g.; F, 30 g.; Cals. 443. Tea: C, 10 g.; P. 6 g.; F, 11 g.; Cals., 168. Evening: C, 20 g.; P, 20 g.; F, 30 g.; Cals., 443. This is called the Maintenance Diet.

If a fast has been given it may be broken in many ways, but the plan set forth on p. 422, known as the "Ladder Diet" at St. Bartholomew's Hospital, is very easy for the unintelligent patient to carry out, and it can be varied very readily by means of the food tables. The value of Diet V. (C, 95 g.; P, 69 g.; F, 75 g.; Cals., 1352) is nearly the same as that of the Maintenance Diet.

Many patients with a mild form of the disease will maintain a normal blood sugar on this diet, and the urine will contain neither sugar nor aceto-acetic acid. In this case the amount of carbohydrate should be cautiously increased by 5 or 10 g., until 130 g. is reached. This amount of food is often sufficient to make thin patients gain weight, but if such should not be the case extra protein (7 g.) should be given every two weeks, until the weight does begin to increase. The fat should not be increased. Very fat patients should continue to lose weight until a reasonable weight for age, height, and sex is attained. The patients should learn how to use the food tables in order to vary the diet, but for unintelligent patients it is usually necessary to prescribe a very simple diet, *e.g.* Diet VI. or VII.

As regards food values, Table I. (shown on p. 426) contains some of the carbohydrate-containing foods, and 5 g. carbohydrate are contained in the following weights of the edible parts of vegetables, fruits and nuts. The vegetables are cooked, unless otherwise stated. Any one item, therefore, may be substituted for any other without risk of serious error.

Now that the diet contains 100-130 or more grammes of carbohydrate, it is unnecessary to prescribe the so-called diabetic bread or cake. One ounce of some of these foods contains 10–12 g. of carbohydrate, in comparison with the 15 g. of one ounce of white or brown bread. Diabetic jellies, jams and marmalades all contain a little glycerine, but the amount is so small that it may be neglected.

Insulin.—Insulin should be administered if the urine still contains sugar, or if the fasting value of the blood sugar is above 200 mg. per 100 c.c., after the patient has eaten the Maintenance Diet for three days, or has reached Diet III.

The correct dose of insulin can be discovered very easily if an estimation of the blood sugar can be made. If this is not possible, treatment with insulin can be carried out, provided the urine is collected in 3-hourly periods (approximately) and tested for sugar. So long as the blood sugar is below the threshold of the kidney, *i.e.* 180 mg. per 100 c.c., the urine will not contain any sugar (see Fig. 10). Each succeeding specimen should then be tested, so as to be able to determine when the blood sugar rises above

180 mg. per 100 c.c. again. By this method it is possible to ascertain that the fasting value of the blood sugar is below 180 mg. per 100 c.c., but it is not possible to determine whether it is normal or not without making an estimation. The initial dose of insulin should be 5–10 units; and if after 3 days each specimen of urine contains sugar, the dose should be increased by 2 units every day until the dose is 12 units. If the disease is severe the patient should be in bed, but if the disease is mild this is unnecessary. The diet and insulin should be supervised by a trained nurse. If this amount of insulin is not sufficient to render the urine sugar free, 5 units of insulin should be given about 7 p.m. The evening dose should then be increased by 2 units every second day, so long as the urine passed before the morning dose of insulin contains sugar. As soon as the dose of insulin is nearly adequate, the urine will be free from sugar, except immediately before and after each dose

of insulin. When the evening dose has been increased to 12 units without getting rid of the sugar, the morning and evening doses should be increased alternately by 2 units every 2 days, until the urine is sugar free. The estimation of the blood sugar is of great assistance in difficult cases. The best time of day to estimate it is before each dose of insulin and 3 hours after the morning dose. The great majority of patients need 10–20 units, but some need 100–200 units and occasionally as much as 400 or more units a day. After the fasting value of the blood sugar has been reduced to normal and the urine is sugar free all day, symptoms of hypoglycæmia may appear. The patient himself should be able to recognise these symptoms, and also should know how to treat them, either with orange juice, or two lumps of sugar, or adrenaline, 1 c.c., or pituitary (posterior lobe) extract, 1 c.c. (see p. 423). Some patients do not recognise the manifestations of hypoglycæmia, and are liable to develop serious symptoms. In these cases it is advisable to reduce the dose of insulin, and allow a little glycosuria to occur before each dose of insulin, but the urine passed between 1 and 5 p.m. should be free from sugar. The dose of insulin which caused the hypoglycæmia should the next day be reduced by 2 units. When the blood sugar is normal, the carbohydrate should be increased, every 3 or 7 days, by 10 or 15 g. portions up to 110 g. It is usually necessary to increase the insulin at the same time, in the proportion of 1 unit to 4 g. of carbohydrate. When this extra carbohydrate has been correctly balanced with insulin, the carbohydrate should be cautiously increased up to 130–150 or 250 g. It may not be necessary to increase the insulin if the patient is showing signs of hypoglycæmia. The extra carbohydrate may be divided among the usual meals, except afternoon tea, but it is often convenient to give 10–15 g. of carbohydrate before going to bed and also in the middle of the morning, if such does not interfere with the patient's occupation. If the patient loses weight in spite of the extra carbohydrate, the protein, but not the fat, should be increased by 7 or 14 g. The maximum amount of fat should not exceed 100 g. for an adult, and some authorities restrict it to 50 g. If the weight is constant, and the patient is not more than 10 per cent. under weight, the caloric value is adequate. If, on the other hand, the patient gains weight rapidly, the protein and fat should be decreased. It is sometimes necessary in cases of tuberculosis, or to meet the patient's tastes, to increase the carbohydrate to 200 or 250 g. In such cases the insulin should be increased in the proportion of 1 unit to 6 or 8 g. of carbohydrate. It may be necessary to give the insulin three-quarters to an hour before the meal, in order to prevent large carbohydrate meals raising the blood sugar too high. Since active exercise often causes hypoglycæmia, it is advisable either to decrease the insulin by 5 units or more, or to increase the carbohydrate by 10 or 15 g. at the previous meal. Sugar, two or three lumps, should always be available for such emergencies. In some cases it is very difficult to keep the blood sugar within normal limits, because it swings from hyperglycæmia to hypoglycæmia, and back to hyperglycæmia in 6 or 8 hours, instead of 10 or 11 hours. If the dose of insulin is increased in order to keep the blood sugar normal for a longer period, the patient will probably have severe attacks of hypoglycæmia at midday. In these cases the morning dose should be reduced by 10 units, and a third dose of 8 units administered immediately before the midday meal.

Intensive research work on the properties and preparation of insulin has resulted in two new preparations: Protamine insulin (trade name Retard or Delay), introduced by Hagedorn; and protamine insulin with zinc, prepared by Scott. Protamine insulin has no immediate effect on the blood sugar, but begins to work after 4 hours or so, and its effect lasts for the next 8 to 12 hours or in some cases for 24 hours. Protamine insulin with zinc does not commence to have any effect for the first 8 to 12 hours, but it continues to act for the next 14 to 16 hours or even longer. Both these insulins are now used in the treatment of patients and are very useful. The protamine insulin with zinc, either alone or in combination with ordinary insulin, will often control the blood sugar by means of only one injection in the morning. If a patient is well balanced on 20 units in the morning and 16 units at night, the change should be made to 20 units of ordinary and 12 units of protamine insulin with zinc; the reduction of 4 units is necessary to prevent the patient having overdosage, as the protamine is more efficacious. The patient is then liable to hypoglycæmia at three times in the day—before the midday meal as the result of the ordinary insulin, before the evening meal due to the protamine insulin with zinc beginning to act, and during the night when it is very active. This last reaction may come either early in the night or as late as just before breakfast. The amount of carbohydrate should be adjusted to overcome this liability to overdosage. An extra 10 or 15 g. should be given at tea-time, before going to bed, and before the morning injection of insulin. This will entail an increase of between 30 and 45 g. of carbohydrate, but this is usually well tolerated in spite of the initial reduction of the dose of insulin. The change is facilitated by the estimation of the blood sugar, but it can be achieved without this if the urine is tested regularly every 3 hours during the day, on waking, and before breakfast is eaten.

The following rules are of value:

Rules for Decreasing the Insulin in Cases of Overdosage

(1) If there are any signs of overdosage at midday, the dose of ordinary insulin should be decreased by 2 units, or if severe by 4 units.
(2) If there are any signs of overdosage between midday and the evening meal, the dose of each insulin should be reduced by 2 units, or if severe by 4 units.
(3) If there are any signs of overdosage between the evening meal and the next morning, the dose of protamine zinc insulin should be diminished by 2 units, or if severe by 4 units.

Rules for Increasing the Dosage of Insulin

(1) If the urine passed at 8 a.m. contains sugar, it means that the dose of protamine zinc insulin was insufficient and should be increased by 2 units every third day.
(2) If the urine passed at 7 p.m. contains sugar, it means that the dose of ordinary insulin was insufficient and should be increased by 2 units every third day.

The proportion of the two kinds of insulin varies, for in some cases equal amounts of soluble and protamine insulin with zinc are needed, while in others much soluble and little protamine, or little or no soluble and much protamine insulin with zinc, are necessary. Some patients can be well controlled with the mixture of insulins, and the doses of the insulins can be gradually reduced. If the case is difficult to control, the patient should be allowed to pass sugar before breakfast and before the evening meal. In these cases better results can often be obtained with a mixture of protamine (Retard or Delay) and soluble insulin twice daily, as this is equivalent to giving four doses of insulin a day. Thus, if a patient is passing much sugar at 8 a.m. and yet after 30 units of soluble insulin has symptoms of hypoglycæmia at midday and again passes much sugar at 7 p.m. he can be helped if the dose of soluble insulin is reduced to 20 units and 10 units of protamine administered at the same time. This will prevent the hypoglycæmia at midday, and also tend to prevent the blood sugar from rising so high at 7 p.m. Similarly, if the blood sugar is very low at night and high before breakfast, the evening dose is diminished by 10 units and 10 units of protamine insulin are given. By varying the dose of the two different kinds of insulin it is often possible either to control the glycosuria and hypoglycæmia completely, or to lessen considerably the inconvenience of the attacks of hypoglycæmia.

It is not possible to say which combination of soluble and protamine insulin will be most effective, as this can be discovered only by trial and error. Some patients need a mixture of both insulins night and morning; others, protamine at night and a mixture of the insulins or soluble only in the morning; and others, either a mixture of the insulins or protamine alone at night, and another combination will be necessary in the morning.

Further advances with the different kinds of insulin may be expected, and the lot of the diabetic patient will consequently be further improved.

The *after-treatment* is very important. The patient should be taught as much as is possible about the disease and diet, for if he understands the principles concerned, he is much more likely to carry out the treatment correctly. He should also be taught to test the urine with Benedict's solution. If no insulin is taken the urine passed after the evening meal should be tested, but if insulin is used the urine immediately before the injection in the morning or evening should be tested.

Medicinal treatment.—Many preparations of the pancreas or of herbs which can be taken by mouth are extensively advertised. With one exception they are all valueless as well as being expensive. Synthalin, 40 mg., with decholin, 25 mg., given for 3 days at a time with one day's rest, has a definite though slight action on the glycosuria and glycæmia in many cases. It has the great disadvantage that it often causes toxic effects, such as dyspepsia, vomiting and jaundice. It should not be recommended unless the patient refuses insulin. Purgatives are of great importance, and the necessity of an efficient daily evacuation should be insisted on. Ext. aloes, gr. 4, ext. nuc. vom., gr. $\frac{1}{4}$, in pill form, one to two at night; inf. of senna pods, ten to thirty; phenolphthalein gr. 4 to 8 or more in liquid paraffin 1 fl. oz. b.d.s., are the most efficacious; salines, together with tinct. jalapæ co. min. 30, should only be used in emergencies. General tonics which improve the health may be used. Opium used to be of assistance in the late stages of the disease, but should not be required nowadays.

TABLE I.

A. VEGETABLES

Group 1—

(These need not be weighed as they contain so little carbohydrate):

Asparagus	16
Cabbage	18
Cauliflower	15
Celery (raw)	14
Cucumber (raw)	9¾
French Beans	16
Lettuce (raw)	9¾
Mustard and Cress	20
Rhubarb	18
Radishes (raw)	6¼
Sea-Kale	29
Spinach	13
Watercress (raw)	25
Brussels Sprouts	10
Marrow	13

Group 2—

Beans, broad	2½ oz.
Beans, Haricot	1
Beetroot	
Carrots	4
Leeks	4
Onions	6
Parsnips	1½
Peas (dried)	1
Peas (green)	2
Potatoes	1
Turnips	7

B. FRUITS

Apple (raw)	2
,, (cooked)	4
Apricot (fresh, with stone)	3
Banana	1
Blackberries	3
Cherries (with stone)	1½
Damsons (with stone)	2
Gooseberries (raw ripe)	2
,, (unripe, stewed)	10
Grape Fruit	3½
Grapes	1
Greengage (with stone)	1½
Melon	3½
Oranges	2
Peaches (with stone)	2
Pears	2
Pineapple (fresh)	1½
,, (tinned)	½
Plums (with stone)	2
Raspberries	3
Red or Black Currants	3½
Strawberries	3
Tomatoes	6
Jam or Marmalade	¼

C. NUTS

Almonds	1 oz.
Chestnuts	2
Hazel Nuts	1½
Walnuts	1½

D. STARCHY FOODS

Milk	3½ oz.
Bread	
Dry Oatmeal	
Force or Cornflakes	
Rice	
Plain Biscuit	

The following contain little or no carbohydrate:

Tea	Lemon Juice	Meat Extract	Vinegar
Coffee	Soda Water	Gravy Soup	Saccharine

TABLE II.—PROTEIN AND FAT

The following articles of food contain approximately 6·5 to 7·0 g. protein, and 6·5 to 7·0 g. fat, and may be substituted for each other without causing serious error:

oz. Beef.
Mutton.
Pork
Lamb.
1½ ,, Tripe
,, Veal.
Egg.
oz. Sardines.
,, Salt Herring.
,, Salmon.
,, Chicken with the addition of ¼ oz. Butter.

1 oz. Rabbit, with the addition of ¼ oz. Butter.
1 ,, White Fish, with the addition of ¼ oz. Butter.
1 ,, Ham.
1 ,, Cheese.
1½ ,, Bacon, but ¾ oz. Butter should be deducted from the Butter ration.
2½ ,, Bread.
6 ,, Milk.

Fat, 5 oz. cream = 1 oz. Butter.

g. Protein = 4·1 Calories.
Carbohydrate = 4·1 ,,
,, Fat = 9·3 ,,
,, Alcohol = 7 ,,

6·25 g. Protein = 1 g. Nitrogen.
1 kg. = 2·2 lb.
30 g. or cubic centimetres (c.c.) = 1 oz.

A patient at rest requires 25 calories per kilo body-weight per 24 hours, approximately 1 calorie per kilo per hour.

Complications—Coma.—This requires prompt and energetic treatment with large doses of insulin. The patient is sometimes very cold and collapsed, and he should be made warm as soon as possible, by means of a hot air bath, or, if this is not available, by hot water bottles, as in the treatment of surgical shock. The blood sugar is usually high, 300–800 mg. per 100 c.c., and it is safe to give 50–100 units of insulin, subcutaneously, as soon as the diagnosis is made without waiting for a blood-sugar determination. If the condition is very grave, the insulin should be given intravenously. If it is not possible to estimate the blood sugar, a dose of 50 g. (2 ounces) of dextrose should be given by mouth or by an œsophageal tube, and 50 to 75 units of insulin. If there are no signs of returning consciousness in 3 hours, another 50 or 70 units of insulin, together with 50 g. of dextrose in solution, should be given. The urine should be collected every 3 hours. If it is necessary to pass a catheter, a self-retaining one should be used and the urine tested every hour. The urine for the first 3 hours after insulin is certain to contain sugar, and if the urine for the 4th to 6th hours contains sugar, it is safe to give 30 to 50 units of insulin. If, however, the urine for the 4th to 6th hours does not contain sugar, it is dangerous to give any more insulin, unless sugar, in the proportion of 4 g. to 1 unit of insulin is given by the mouth or intravenously at the same time. If there is any doubt as to whether the patient is recovering, this latter procedure should always be followed. If the condition, however, is improving, no insulin should be given until sugar reappears in the urine. Water in as large amounts as is possible, either by mouth or by nasal catheter, should be given; at least 10 ounces each hour for some 6 hours. If the condition is grave, especially if the patient is vomiting, the fluid should always be administered by an intravenous drip. A solution of 10 per cent. dextrose in $\frac{1}{4}$ normal saline should be given. 2000–3000 c.c. should be administered in 24 hours if nothing is taken by mouth. An estimation of the hæmoglobin should be made at intervals, in order to determine whether sufficient fluid is being given or not. Two ounces of castor oil should be given with the first drink, as these patients are nearly always very constipated. In coma the alkali reserve is always much reduced, and sodium bicarbonate is of assistance, although the enormous doses which were administered before the discovery of insulin should not be given. A dose of 12 g. (3 drms.) 600 c.c. of 2 per cent. sodium bicarbonate should be given intravenously, and no advantage is to be gained by giving a bigger dose.

Every patient in coma should be examined most carefully each day, in order to determine whether any other disease is present. In 7 out of 9 cases admitted to St. Bartholomew's Hospital in the first year of insulin treatment, an acute infection, *e.g.* acute otitis media, parotitis, or gangrene of the lung, was present. The appropriate treatment should be instituted as soon as possible.

Acute infections, such as influenza, usually cause a considerable diminution of the sugar tolerance. If the infection is of mild degree, it may be sufficient to increase the dosage of insulin by 2 or 4 units for some days. If, however, the infection is of severe degree, it is important that the condition should be adequately treated, so as to prevent (1) any danger to life, and (2) any permanent diminution of the sugar tolerance. The same procedure should be adopted as in the treatment of coma (Fig. 11), but the dose of insulin should be much smaller, unless the patient is very ill. Provided the urine is collected

in 3 hourly periods and tested for sugar, a sufficient dose of insulin may be given with safety every 6 or 9 hours, and thus the ill-effects of the infection reduced as much as possible.

Surgical operations were always contra-indicated before insulin was known, but they may now be carried out, provided certain precautions are observed. The patient's blood sugar should be reduced to normal, provided that there is time to achieve this. Gas and oxygen, local or spinal anæsthetics cause no ill-effects. Neither ether nor chloroform should ever be given alone, but the former may be given with gas and oxygen, if deep anæsthesia is required, but as little as possible should be used. Fifty g. (2 oz.) of sugar, together with 16 units of insulin (1 unit to 4 g.), should be administered about 2 hours before the operation, in addition to the usual dose of insulin, in order to have plenty of sugar and insulin in the body at the time of operation. After the operation the appropriate diet for the surgical disease, together with adequate amounts of insulin, should be given for the first few

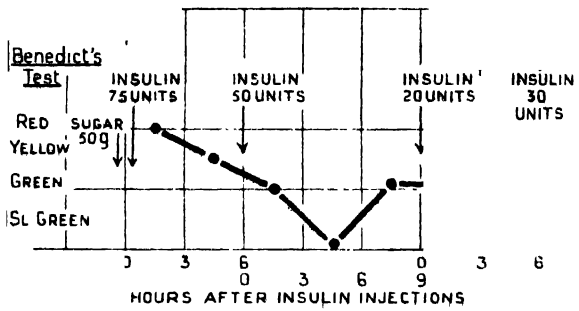

Fig. 11.—Figure showing how an adequate dose of insulin can be arrived at by testing the urine in a patient in diabetic coma.

days, but as soon as possible the usual diabetic diet should be given and the blood sugar controlled again. If pregnancy occurs it should not be terminated unless there are other complications.

Renal Glycosuria

This is an uncommon condition which is apt to occur in several members of a family. Although the blood sugar lies within normal limits, dextrose may be present in the urine, either throughout the day or only after a carbohydrate meal. The sugar is usually small in amount, *i.e.* less than 10 g. per diem, but several cases are reported in which 20 to 30 g. were excreted in the day. The amount of sugar in the diet has little influence on the total sugar excretion. The diagnosis should only be made after a series of observations. A complete test of the sugar tolerance with doses of 25 to 50 g. of sugar should be made when the patient is eating plenty of carbohydrate food and the urine contains no acetone bodies. Estimations of the blood sugar should be made at intervals of half an hour for 2 to 3 hours after the dose of sugar, and the amount of sugar excreted in the urine should be estimated. If sugar is present in the urine, although the blood sugar does

not rise above 180 mg. per 100 c.c. at the end of 30 minutes and has returned to the normal level after 2 hours, the patient probably belongs to the renal glycosuria class.

The prognosis is good, and no treatment is required once the diagnosis is made. It is wiser to treat all doubtful cases with moderate restriction of the carbohydrate ration (100 g.) and to repeat the sugar tolerance test in 1 to 3 months' time. Very little harm can be done by this procedure, while much damage can be done if a case of true diabetes is treated with no dietetic restrictions (Salomon, Graham).

Lævulosuria

Lævulosuria is a sign of some importance of the liver and should direct attention to that organ. Slight reduction of carbohydrates and of fruits is usually sufficient to check it.

Lactosuria

This occurs (1) during lactation, (2) when suckling suddenly ceases, and (3) in breast-fed infants with enteritis.

Pentosuria

This is a rare occurrence. Many of the patients are Jews. Of 7 cases, 3 were Jews, 2 Greeks, and 2 English (Cammidge).

GOUT

A disease in which there is a disturbance of the purin metabolism and an increase of uric acid in the blood. The clinical sign is an attack of acute arthritis with a deposition of sodium biurate in and about the joints.

Ætiology.—*Predisposing causes.* — Gout is much commoner among certain races, *e.g.* the English and German. It is very uncommon among native races. It does not follow, however, that this is a racial peculiarity. It is much commoner in temperate than in tropical climates, but it is unlikely that the climate plays any part in the causation of the disease. The evidence in favour of gout being an hereditary disease is very strong, as a history of a gouty ancestry can be obtained in 50 to 80 per cent. of the cases. A history of gout in the family was obtained in 75 per cent. of well-to-do patients and in 50 per cent. of hospital patients (A. B. Garrod). This evidence suggests that the disease is chiefly hereditary but may be acquired. It is not the disease which is inherited, but only the predisposition to it, and the disease may lie latent until it is evoked by other causes (Llewellyn). It is a disease of middle life—between the ages of 35 and 50—but it may occur much younger, even in schoolboys who have a strong hereditary taint. The malady is very much more common in men than in women. Women form only 5 to 20 per cent. of the patients in most statistical tables.

Exciting causes.—Food plays a part in the causation of the disease, but it is rather the quantity than the quality which matters. Meat and the purin bodies in tea, etc., probably have little effect, but sweetbreads, liver,

kidneys, fish roes, tripe may be actively harmful. Spirits have little effect, and gout is almost unknown in Scotland. Beer is much more potent and is probably partly responsible for the prevalence of gout in England and Germany. The strong wines like port and sherry, and the red wines such as Burgundy and claret, are also probably responsible for much gout among the well-to-do classes, and champagne has a bad reputation. The light white wines like Graves and hock and cider are less evil. Gout was formerly very common among lead workers in England, and it seems to be a concomitant cause. Trauma plays a great part in the causation of the acute attack. The big toe may be affected so frequently because of the pressure of the boot. An injured joint may be the seat of the first attack of gout. Syringing the ear of a gouty patient for cerumen was followed by an acute attack in the external auditory meatus (A. E. Garrod). Local sources of infection are very common among gouty patients, *e.g.* septic gums and tonsils. These used to be called gouty manifestations, but Llewellyn thinks that they may be responsible for causing the attack of gout.

Physiology and Pathology.—The fact that sodium biurate was deposited in and around the joints suggested that uric acid played an essential part in the causation of gout. After A. B. Garrod had demonstrated by means of his thread test that the blood of gouty patients contained uric acid in abnormal quantities the hypothesis seemed to be proved. The problem is, however, not so simple as was thought at first.

The uric acid which is excreted in the urine of healthy people on an ordinary mixed diet comes from two sources, exogenous and endogenous. When all the exogenous sources of uric acid, *e.g.* meat, fish, sweetbread, tea and coffee, etc., are removed from the diet the output sinks to a level of 0·5 to 0·7 g. per day. The amount is fairly constant for each individual. If all proteins are removed from the diet, the endogenous uric acid output falls to a lower level than before (Folin). The removal of carbohydrates and a reduction of the caloric value of the diet also cause a decrease in the endogenous uric acid output to the lower level (Graham and Poulton). The endogenous uric acid output is believed to come from the breakdown of the cell nuclei of the body, *i.e.* wear-and-tear, but it can also be synthesised from histidin and arginin (Hopkins and Ackroyd). When the exogenous purins are eaten, or when uric acid is injected, there is an increase in the uric acid output, but the whole of the uric acid is not excreted in one day. If cinchophen is given at the same time, the excretion-rate of the uric acid is increased.

The blood always contains uric acid, and the limits of normal variation in health are 1 to 3 mg. per 100 c.c. The total uric acid in the blood of a man weighing 10 st. 3 lb. or 65 kilos would be 50 to 150 mg., assuming that the blood constitutes $\frac{1}{13}$th of the body-weight, *i.e.* 5000 c.c.

In cases of gout there is usually a considerable increase in the amount of uric acid in the blood. Before an attack the blood may contain 4 to 6 mg. of uric acid per cent., though occasionally between the attacks there may be only a slight increase. The uric acid may also be increased in some people who have never had gout; as, in leukæmia, where there is a great destruction of leucocytes, and in severe cases of nephritis. The increase in the uric acid in the blood is, therefore, not pathognomonic of gout, although it is extremely suggestive of it.

In gout the output of uric acid varies widely. It may be quite small in amount, less than 0·20 g. per day, or it may be equal to that excreted by healthy people. Before the attack of gout it is usually very small in amount, but the paroxysm always causes a great increase in the output for a few days only. When purin bodies are eaten by a gouty patient, or if uric acid is injected, there is great delay in the excretion of uric acid. If cinchophen is given at the same time, the uric acid is excreted much more quickly. The diminution in the uric acid output may be due to an increased destruction in the body or to its retention by the kidneys. There is no evidence of increased destruction in the body, as the blood of a patient before an attack may contain 4 to 6 mg. of uric acid per 100 c.c. This suggests that

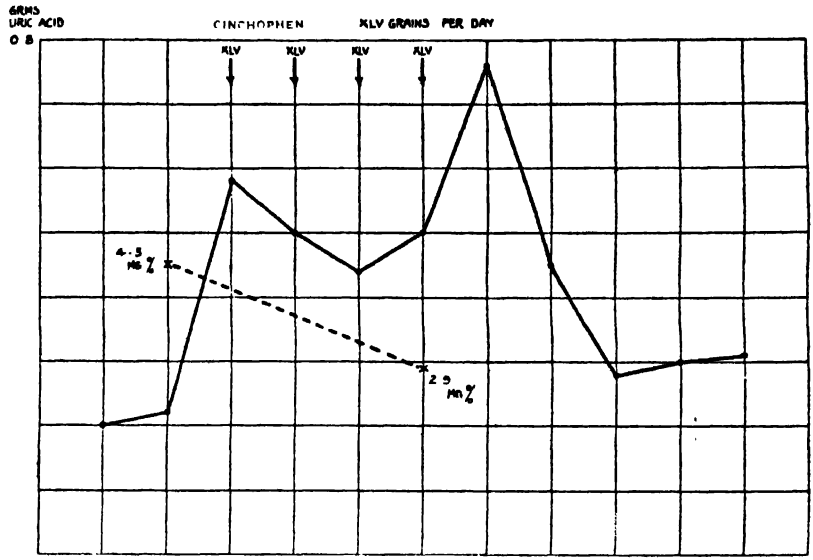

FIG. 12.—Figure showing the increase in the output of uric acid in the urine and the decrease in the uric acid in the blood after cinchophen.

the uric acid is retained by the kidneys. When cinchophen is given to a patient whose blood contains 4 to 5 mg. per 100 c.c. uric acid there is a great increase in the uric acid output and a decrease in the uric acid in the blood (Folin and Lyman). The " extra " uric acid excreted in 6 days (Fig. 12) was 1·9 g., while the blood uric acid decreased from 4·5 mg. to 2·9 mg. per cent. The " extra " uric acid must come from the uric acid in the body fluids, as the blood does not contain enough uric acid (Graham) (Fig. 12).

The evidence points to the view that although gout cannot exist in the absence of excess of uric acid in the blood yet uric acid is not the cause of gout.

The essential change is the deposition of uric acid as sodium biurate in the joints. The sodium biurate appears to be plastered over the surface of the cartilage, but on microscopical examination it is seen that there is a

the uric acid is retained by the kidneys. When cinchophen is given to a patient whose blood contains 4 to 5 mg. per 100 c.c. uric acid there is a great increase in the uric acid output and a decrease in the uric acid in the blood (Folin and Lyman). The "extra" uric acid excreted in 6 days (Fig. 12) was 1·9 g., while the blood uric acid decreased from 4·5 mg. to 2·9 mg. per cent. The "extra" uric acid must come from the uric acid in the body fluids, as the blood does not contain enough uric acid (Graham) (Fig. 12).

The evidence points to the view that although gout cannot exist in the absence of excess of uric acid in the blood yet uric acid is not the cause of gout.

The essential change is the deposition of uric acid as sodium biurate in the joints. The sodium biurate appears to be plastered over the surface of the cartilage, but on microscopical examination it is seen that there is a

layer of cartilage over the deposit, which is always interstitial. The deposits may be quite small or enormous. In many cases the structure of the bones is destroyed and replaced by sodium biurate. The ligaments, tendon sheaths and bursæ are also infiltrated. The big toe joints may contain sodium biurate, although the patient has never had an acute attack of gout. The skin covering a tophaceous deposit may ulcerate and break down, and small masses of sodium biurate may be discharged (chalky gout).

Tophi.—Sodium biurate is also deposited in the cartilage of the ear, especially in the outer margin of the pinna. The tophi appear as white nodules, and uric acid crystals can be recovered from them, which also give the murexide test and a blue colour with Folin's phospho-tungstic reagent.

The kidneys.—An uratic deposit may occur in the pyramids. Norman Moore found it in 12 out of 80 cases. Well-marked changes of chronic interstitial nephritis are often found.

Symptoms.—The earliest sign of gout is sometimes the deposition of sodium biurate in the cartilage of the ear (tophus). This stage usually passes unnoticed, but is sometimes accompanied by an intolerable itching or tenderness.

Acute gout.—The first attack of "classical" gout usually occurs at night. There may have been a few preliminary symptoms, such as dyspepsia, slight pain in the hands, and irritability of temper, but the patient goes to bed feeling well. "The patient suddenly wakes with pain, more or less intense, in the ball of one great toe, frequently accompanied with a slight shivering; the pain in the toe gradually increases and is attended with a sensation of burning, throbbing, together with great tension and stiffness; heat of skin and other symptoms of febrile disturbance usually follow the shivering, accompanied with a considerable degree of restlessness" (A. B. Garrod). The temperature is raised to 101° or 102° F., but after a few hours the patient begins to sweat and finally falls asleep. "In the morning the toe is swollen, the skin shiny, tense and dark red, and the whole joint is extremely painful" (A. B. Garrod). Usually the acute pain lessens in the daytime, but returns with great violence in the night hours. The temperature remains high and the temper of the patient is irascible in the extreme. The attack may last many days or pass away in two days. When the attack is ceasing "the inflamed joint becomes less intense and swollen, and pitting is readily produced on pressure" (A. B. Garrod). The attack may spread from the great toe to the other joints of the tarsus or to other joints of the body. The first joint of the big toe is most commonly affected. The ankles, knees and small joints of the hand and wrists are next in the order of frequency.

During the attack there may be a considerable degree of leucocytosis, 20,000 to 25,000, and all but 2000 to 3000 are polymorpho-nuclear cells as the lymphocytes and other cells are unaltered by gout. The uric acid output, which was low before, is greatly increased for a few days. Sodium biurate is deposited in the cartilage of the joint and head of the bone, but the swelling and stiffness may eventually disappear completely. The acute attack may be complicated by a severe gastro-intestinal disturbance which may be fatal. There may be other symptoms, such as dyspnœa, delirium and coma, but these are probably due to a coincident uræmia. Phlebitis of the veins of the limb may be a complication of an acute attack.

After the attack, whether as the result of illness or as a consequence of

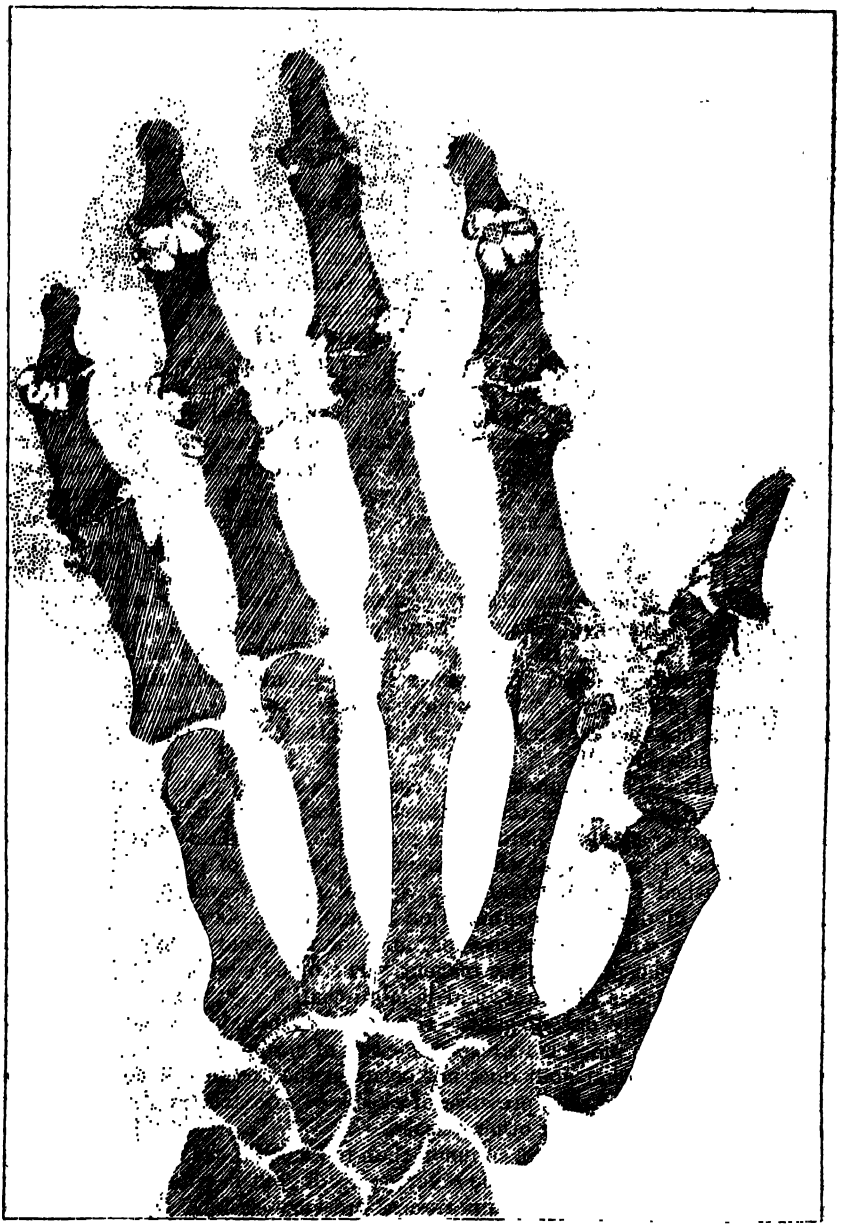

FIG. 13—Line drawing from a radiograph, showing the changes which take place in the bones due to the deposition of sodium biurate.

the simple living which the patient has endured, the general health of the patient is much improved. The attack usually follows in the spring and autumn. The second attack may follow at once, or may be delayed for many years.

Chronic gout.—After several attacks the joint does not recover completely. The deposits of urates occur in the ligament and capsule, as well as in the articular cartilages and bones. The joint, therefore, becomes swollen and irregular in its shape. The urate is especially deposited in the bursæ about the joints. In the advanced stages the skin over the uratic deposits breaks down and masses of chalky material are extruded, and the wounds heal with difficulty. The general health of the patient suffers after several attacks and does not recover completely. Dyspepsia is complained of, and the patient may show signs of high blood-pressure and arterial disease. The urine is increased in amount, and may contain albumin and casts.

Irregular gout.—Almost any symptom or physical sign which occurred in a person who was of a gouty disposition was formerly ascribed to gout. Cutaneous eruptions, such as eczema, gastro-intestinal disorders, cardio-vasular symptoms and pericarditis, headache, migraine and neuralgia, were all thought to be gouty. A gouty patient may develop any of these diseases, but the belief that there is a general type due to gout is now regarded as unfounded. The urine is usually acid, and on cooling often deposits uric acid crystals. This does not mean that there is an excess of uric acid in the urine, but that the urine is too acid to keep the uric acid in solution. On heating the urine the urates are re-dissolved. Gouty persons may suffer from calculi. Glycosuria occurs in some cases, but usually responds readily to treatment. Albuminuria and casts are present when the kidneys are also affected. Elderly persons often suffer from chronic bronchitis. Gout has been accused of rendering patients more disposed to iritis, retinitis and glaucoma. It is possible that iritis and retinitis have a gouty basis though they may arise independently.

Diagnosis.—The diagnosis in a case of classical gout, with recurring attacks of arthritis in the toe or tarsus, is easy, especially if the patient comes of a gouty stock or indulges in good food and drink. The presence of tophi is proof positive that the patient is a subject of gout. Tophi must be distinguished from Woolner's tip, fibroid nodules and sebaceous cysts, and in cases of doubt an examination should be made for the crystals of sodium biurate with the microscope, and for uric acid with the murexide test or Folin's phospho-tungstic reagent. The blood should be examined for uric acid in all cases of doubt, and if more than 3 mg. per cent. are found the case is probably one of gout. It must be remembered, however, that the uric acid in the blood is increased in cases of chronic interstitial nephritis. While it is certain that gout does not occur in the absence of an increase of uric acid in the blood, the presence of excess of uric acid in the blood does not exclude the presence of other diseases.

Classical gout is much less common than it was, and the modern tendency is to overlook the disease. In the severe cases of gout in which the joints are severely damaged, the X-ray appearances are very striking (Fig. 13). The negative shows dark areas where the sodium biurate is deposited in large amounts and replaces bone or cartilage, since sodium biurate is not opaque, like the calcium ion. In the less severe cases there may be—(1) lipping at

the articular margins; (2) a localised atrophy of the bone; (3) a narrowing of the joint space. These changes occur in other kinds of arthritis and are in no way characteristic of gouty arthritis (Llewellyn).

Prognosis.—If a patient has once had an attack of gout he will always be liable to another attack, unless he alters his way of living. The frequency and severity of the attacks can be modified by treatment. The prospect of long life depend upon the state of the heart, arteries and kidneys.

Treatment.—*Dietetic.*—In perhaps no other disease have a greater number of dietetic fads been recommended. The total quantity of the food should be kept within reasonable limits, and civic dinners should be avoided. The meals should be simple but attractive. There is little difference between the different kinds of meat, except that for those who have dyspepsia chicken is more easily tolerated than beef and mutton. There is no need to deprive the patient of sugar, which is a common fad, or of starchy food, but they should be eaten in moderation. The same is true of fat. Some gouty persons are much too stout, and a reduction of weight is beneficial.

All protein foods contain purin, but their content varies widely (see table below). The foods which contain more than 0·1 g. per 100 g. should be avoided, as the uric acid which is formed from the breakdown of the purin is excreted more slowly by the gouty patient than by the healthy one.

THE PURIN CONTENT OF VARIOUS FOODS (R. A. M'CANCE)

Material (All cooked)	Purin Nitrogen per 100 g. of Edible Food
Brains	0·033
Mutton (general average)	0·063
Fish (,, ,,)	0·065
Pork (,, ,,)	0·069
Beef (,, ,,)	0·081
Birds (,, ,,)	0·094
Hearts	0·116
Cod roe (hard)	0·120
Livers and kidneys	0·140
Herring (no roes)	0·150
Smelts	0·168
Sprats	0·180
Sardines	0·234
Whitebait	0·323
Throatbreads, Sweetbreads, etc.	0·426
Herring roe (soft)	0·480

Attacks of gout have followed very quickly after eating sweetbreads and after the administration of purins for experimental purposes. The fruits and vegetables which contain an excess of oxalates, *i.e.* strawberries, rhubarb, spinach and asparagus, should be forbidden if oxaluria is present.

Heavy beers, strong wines like port and sherry, all red wines, and also

champagne, should be forbidden for gouty patients. The white wines, like Graves and hock, may be allowed in moderation if especially desired. If drunk in moderate amount and well diluted, whisky is probably the least harmful beverage. Mineral waters may be of considerable benefit to gouty persons. Their mode of action is uncertain, but is probably due not so much to the ingredients of the waters as to the amount of water drunk, the simple and restricted diet, and the regular and supervised life which the patient leads at a spa. Hot baths and douches are of assistance in aiding the recovery of stiff joints. The waters of Buxton and Bath in England, Vichy, Aix-les-Bains and Contrexéville in France, Wildbad and Homburg in Germany, Carlsbad and Marienbad in Moravia, and Saratoga, Bedford and White Sulphur in America, are the best known.

Local.—During the acute attack the joint should be covered with cotton-wool, placed on a pillow, and the bedclothes raised by means of a cradle. Hot fomentations or cold lotio plumbi c. opio may be applied.

Internal.—The treatment should be started with a purgative, and calomel is recommended. Colchicum is specific for the acute attacks. The pain is usually relieved quite quickly, and the redness of the skin and swelling of the joint subside. Fifteen to 30 minims of the tincture in an alkaline mixture should be administered every 4 hours. The drug may cause vomiting or purgation, and its action must be carefully watched. Its mode of action is quite unknown, and it is of no value in averting an attack. Cinchophen (Trade names : atophan, agotan, phenoquin, quinophan) is useless in relieving the pain of an acute attack, but it is most useful in averting attacks. It is given in tablet form, gr. 15 three times a day for 1, 2 or 3 days consecutively in each week and should never be given continuously. It increases the output of uric acid in the urine and decreases the amount of uric acid in the blood, and thus prevents the continuous accumulation of uric acid in the body. The drug may, however, produce unpleasant symptoms, such as urticaria, dyspepsia and jaundice. The complication of jaundice may be a very serious matter, for acute yellow atrophy of the liver may develop and death ensue. These toxic effects have usually, but not always, occurred : (1) when the drug has been given continuously, *i.e.* without an intermission of 4 to 5 days between the courses ; and (2) when its administration has been continued after minor symptoms of toxic action have appeared. The results of the treatment of undoubted cases of gout with cinchophen are so good that its toxic action is most unfortunate. It would seem that its use should be restricted to the treatment of gout, and only given in short courses each week and discontinued at the first indication of intolerance. Further, as soon as the acute joint condition has passed, the dosage should be reduced to 15 gr. twice a day, one day each week for 2 to 3 months. In a long-standing case, it should then be given once a month, or once in 3 months for an indefinite period. Aspirin and sodium salicylate have a similar action to cinchophen and may be used instead of it. Aspirin gr. 10 with glycine gr. 20, is given three times a day for one or two days each week in the chronic case, or more frequently if an attack is threatening.

The general health of the patient must be attended to and all causes of sepsis should be removed. Radiant heat and massage are very useful for restoring the movements of a crippled joint.

OBESITY

Obesity is a condition in which there is an excessive amount of body fat.

Ætiology.—Certain races are more prone to become fat than others, *e.g.* the Dutch, South Germans, South Italians, Maltese, Hebrews, the natives of India and Ceylon, and some African races. A clear history of heredity was obtained by Futcher in 60 per cent. of his cases. Obesity may develop at almost any age, but it is more likely to occur at certain ages: in babies, in children at puberty, in men after the age of 40, and in women during pregnancy or after the menopause. It is commoner among females than males.

Pathology.—The deposit of fat indicates that the caloric value of the diet is in excess of the individual's needs. This may be due to the large amount of food which is eaten, or to a small energy consumption in the body. Some fat people have a very large appetite and eat much more than is necessary to satisfy their energy requirements. The amount of exercise which is taken has a great influence on the amount of fat which is deposited. Thus, a patient who is lying in bed will gain in weight on a diet which contains less caloric value than that which he eats when he is up and about. Although many cases of obesity are easily explained on the above grounds, there are many instances which cannot be explained so simply.

The investigations of the basal metabolism help us to understand many of these cases. The amount of oxygen which is burnt depends on the state of the patient. More combustion of oxygen takes place when the patient is taking exercise than when he is at rest, and when he has a meal than after a short fast. The metabolism of the resting, fasting individual is termed the basal metabolism. This is expressed in cubic centimetres of oxygen per minute per square metre of body surface. The basal metabolism (p. 403) is lower for adults than for children, and gradually decreases with each decade. It is lower for females than males. The basal metabolism can be altered by prolonged undernutrition and by the influence of the ductless glands. One of the results of underfeeding is a lowering of the basal metabolism, but the oxygen consumption of such a patient during exercise is unaltered. The action of the thyroid gland on the basal metabolism has been carefully studied, as there are two clinical conditions in which the thyroid plays an important part, namely, (1) in hypothyroidism, and (2) hyperthyroidism. In the first, the patients, among other symptoms, tend to increase in weight, and the basal metabolism in these cases is much lower than usual. In the second, one of the prominent complications is the rapid loss of weight which occurs, and the basal metabolism is much increased in these cases, and can be increased by giving thyroid extract and decreased by removal of large portions of the gland. When the basal metabolism is low, it is clear that the patient will tend to get fat, although he is eating less food than a patient whose basal metabolism is high. These experiments help us to understand many cases of obesity.

The action of the other ductless glands is not so well understood. When the posterior lobe of the pituitary gland is damaged by a tumour, considerable changes take place in the metabolism. The patients grow fat, and the fat is deposited in the characteristic feminine situations, *i.e.* the breasts and hips in male and female patients (Fröhlich's syndrome). When the anterior

lobe is removed in dogs there is an increase in the weight of the animal (Cushing).

The sex glands have a considerable influence on the metabolism. When the glands develop at puberty there may be an increase or decrease in the fatty deposits. The female lays down fat around the breasts and hips, and assumes the characteristic feminine form. Removal of the testicles, as in eunuchs, usually causes an increase in the body-weight. During a pregnancy women often grow stout long before they have to restrict their normal activities, while after the pregnancy is terminated, the patient may lose weight, and recover her figure. At the menopause many women tend to become stout.

In obesity the fat is deposited in the subcutaneous tissues, the great omentum, mesentery, and around all the organs, such as the heart and kidneys.

Symptoms.—The presence of large deposits of fat limits the activities of the patients and destroys their good looks. Many of the patients feel well, but some complain of difficulty in moving about, because of their great bulk. Others complain of shortness of breath on the least exertion. Some of the patients are anæmic. Eczema may occur on those parts of the skin which touch each other.

Treatment.—*Dietetic.*—If the patient has only gained a little weight, moderate restriction of the carbohydrate and fat of the diet, together with an increase of exercise, may be sufficient. This is the basis of the well-known Banting cure. When the obesity is considerable, more drastic treatment is necessary if the patient really wishes to lose weight. The treatment may be started in two ways. (1) With a fast day, when the patient should stay in bed. Tea and coffee, with milk and sugar, and gravy soups may be taken in any quantity. The fast day will often cause an initial drop of 1 or 2 lb. in weight and also a reduction in the size of the patient's appetite. The fast day should be repeated once a week, and after a few times the patient need not stay in bed. (2) With a fruit day. A sufficient amount of fruit and vegetables is taken to provide 80 g. of carbohydrate (see Food-Tables, p. 426). The fruit day causes less discomfort than a fast day, partly because of the bulk of the food eaten and partly because the carbohydrate maintains the blood sugar at the normal level, and so prevents the formation of acetone bodies. The patient will be more willing to repeat a fruit day than a fast day once or twice a week.

The three components of the diet, *i.e.* fat, carbohydrate, and protein, should be reduced in different proportions. The fat should be reduced as much as possible, because it has a very high caloric value and the patient has already an excess of fat in his body. Butter, cream, the fat of meat, and especially that of ham and bacon, should be avoided. Chicken is better than mutton or beef, as it contains less fat, while white fish contains no fat. The carbohydrates should be considerably reduced, but this must be done cautiously; for many patients are made miserable, complaining of lassitude and extreme hunger. This is probably due to the blood sugar being too low, since these symptoms occur as a result of an overdose of insulin (p. 413). The protein should be reduced least of all, for its combustion causes an increase in the metabolism of the body—the specific dynamic action of proteins. The total caloric value of the diet may have to be reduced to 1500 calories

(carbohydrate (C), 150 g.; protein (P), 70 g.; fat (F), 64 g.); 1000 calories (C, 100 g.; P, 70 g.; F, 32 g.); 500 calories (C, 60 g.; P, 40 g.; F, 10 g.) (see Table of Food Values) before the patient begins to lose weight. The weight should not be decreased too rapidly. When the fat in the diet is small in amount the patient will suffer from a lack of vitamins A and D. This should be given in the form of radiostoleum, or adexolin, min. 3 once daily. A decrease of 1 to 2 lb. a week and 7 to 8 lb. a month is sufficient. The treatment should be persevered with until the patient's weight is about the average for the height and age. The patient should be encouraged to take more exercise, but this should stop short of inducing undue shortness of breath. Physical drill and massage are of considerable assistance in increasing the energy needs of the body. Care should be taken not to eat more than usual after exercise, for this will neutralise any good effects of the exercise.

Thyroid has been used in the past rather indiscriminately, as it increases the basal metabolism. If the patient has a low metabolic rate (B.M.R.), it should be prescribed; but if the B.M.R. is already normal, it may cause harm. The usual dose is 1 to 2 gr. twice daily. A careful watch should be kept for the onset of tachycardia, tremor, sweating, and glycosuria. When the B.M.R. is raised, more insulin has to be provided, and an elderly patient with a low sugar tolerance may develop glycosuria and have the symptoms of diabetes mellitus as the result of the administration of thyroid.

LIPODYSTROPHIA PROGRESSIVA

This is a rare condition, in which the subcutaneous tissues of the upper part of the body lose their fat, while those of the lower half remain unchanged.

Ætiology.—Females are affected more often than males. The cause of the condition is quite unknown.

Symptoms.—The patient feels perfectly well, but complains that the appearance of the face has altered, having become much thinner. The arms and trunk may also be similarly affected. The condition starts in the face and gradually descends to the arms and trunk. The legs are usually unaffected. On examination, the skin can be picked up easily and it is obvious that there is no fat in the subcutaneous tissues. The malar bones are very prominent. The whole appearance of the patient suggests a severe wasting disease. The breast and mons veneris in females are usually unaffected.

Course.—The condition progresses slowly.

Diagnosis.—This is made by comparing the subcutaneous tissues of the upper half of the body with those of the lower. The presence of a severe wasting disease must of course be carefully excluded.

Treatment.—Nothing is known which has any effect on the condition. The patient should be assured that no serious disease is present.

THE LIPOMATOSES

Localised deposits of fat may occur in many situations. Various types with special symptoms have been prescribed, but it is probable that they are only

variations of a common morbid process.[1] The main types of the disease are:

1. *Adiposis dolorosa* (*Dercum's disease*).—See p. 440.

2. *Nodular circumscribed lipomatosis.*—The lipomata may be few in number or very numerous, symmetrical or asymmetrical, large or small. Most of them are painless, but some are very tender and painful. Asthenia and mental changes, such as occur in adiposis dolorosa, may be present.

3. *Diffuse symmetrical lipomatosis of the neck*—This condition occurs chiefly in males, and the tumour usually appears after the age of 20. The thyroid and pituitary glands showed pathological changes in two cases. The fatty tumour is diffuse and symmetrical. The common sites are beneath the chin, at the nape and base of the neck, and the pre- or post-auricular region, and occasionally on the trunk. The tumour bears no relation to the general obesity of the patient. It is usually complained of because of the disfigurement which is caused. Pain, asthenia and mental disturbances may be present.

4. *Neuropathic œdema, pseudo-œdema, pseudo-lipoma.*—Swelling of the limbs may occur in patients with hysterical affections. This resembles at first sight an œdematous swelling, but it does not pit on pressure. It is due to a deposition of fat in the subcutaneous tissues.

Treatment:—This is very unsatisfactory. Thyroid gr. 1 t.d.s. has given the best results, but pituitary (posterior lobe) extract should be also given a trial. Aspirin may relieve the pain.

GEORGE GRAHAM.

SECTION VII

DEFICIENCY DISEASES

VITAMINS

A COMPLETE and balanced diet must contain a sufficiency of each of the vitamins as well as the correct amount and proportion of protein, fat, carbohydrate and mineral salts. In the absence of vitamins from the diet the so-called deficiency diseases, scurvy, rickets, beriberi and pellagra and other syndromes arise. Vitamins are present in only minute amounts in various foods and were simply described by the letters, A, B, C, D, etc. Nearly all have been isolated, their chemical constitution established, and synthesised by chemists, and they have been more suitably named according to their properties and functions. The list of vitamins is as follows:

Fat soluble.

A = axerophthol
from carotene.
D =
from 7-dehydrocholesterol.
D_2 = calciferol
from ergosterol.
D_3 = same as D.
D_4, D_5 } from other sterols.
E = α- and β-tocopherol.
K =
methyl phytyl naphthaquinone.

Water soluble.

B_1 = aneurine or thiamine (F).
B_3, B_4, B_5 } not yet identified.

B_2 complex:

B_2 (G) = riboflavin.
B_6 = adermin (H).
B_7 = nicotinic acid or amide.
C = ascorbic acid or cevitamic acid.
P is doubtful.

VITAMIN A OR AXEROPHTHOL

The presence of an unknown substance in fats became obvious from the normal growth of rats on some fats, but not on others. Animal fats, except lard, and the fat of green leaves promoted growth, while vegetable fats extracted from seeds did not. The growth-promoting values of the fats were very different, the very high value of cod-liver oil being most striking. Green leaves were superior to butter. The vitamin A value of milk was low, and was derived from the green food of the animal. Green leaves, carrots, and other parts of plants contain the substance carotene, formed in the plant at the same time as chlorophyll. Carotene has also

growth-promoting properties, and yet it is not vitamin A. The connection between carotene and vitamin A was shown by Moore, who proved that carotene was converted in the liver into vitamin A. Three varieties of carotene are distinguished, α, β, γ, of very similar formulæ. β-carotene yields two molecules of vitamin A; the others only one. Other carotenoid pigments in plants are also precursors of vitamin A. The chemical formulæ of these pigments and of vitamin A show clearly how the latter is derived from the carotenoids. Vitamin A (as well as carotene) is stored in the liver; body fat stores very little of it. Storage of vitamin A is helped by fat in the diet. Normal human liver contains 200 international units per gram of wet tissue: at birth, however, the liver contains very little vitamin A. Vitamin A_2, a slightly different compound, is found in the livers of fresh-water fish.

On account of the numerous precursors in plants and different forms in which vitamin A (an alcohol) may exist in animals, chemical methods of estimation of vitamin A values of foods are difficult. The estimation has to be made by feeding experiments. As standard, pure β-carotene is used; 0·6 microgram (millionth of a gram, μg.) is one international unit. One gram of axerophthol from fish livers equals 3,000,000 int. units. The approximate values of some foods are: halibut-liver oil, 16,000,000; cod-liver oil, average 200,000; calf's liver, 46,000; ox liver, 16,000; spinach, 13,000; cream cheese, 4600; butter, 2600; egg yolk, 3000; cheddar cheese, 5500; milk, 2300 international units per 100 grams or 3½ oz.

The daily requirements of adults are reckoned as from 3000 to 4000; of infants 2000 to 2500; and of older children and nursing mothers 4000 to 6000 int. units.

In the absence of vitamin A from the diet, young animals cease to grow, and as soon as stores in the body are exhausted become very susceptible to bacterial infections entering through the mucous membranes. The function of the vitamin is to keep healthy the moist surfaces of the epithelia and prevent hyperplasia, metaplasia, and keratinisation. If the supply of vitamin A is insufficient the fur of animals and feathers of birds become dry and ruffled, and the first visible symptoms are a peculiar and characteristic eye disease similar to xerophthalmia which had been observed in children. The eye disease is a special instance of keratinisation. The only treatment is vitamin A in cod-liver oil or other fish-liver oil. Local treatment is of no avail. Cases of xerophthalmia were described by Budd in 1842, recorded by the explorer Livingstone in Africa in 1857, and Bloch, 1917–1924, observed many cases in Copenhagen.

After the eye symptoms, diets low in vitamin A lead to respiratory infections and broncho-pneumonia. Abscesses at the base of the tongue, suppurating glands, pus in the middle ear, septic nasal sinuses, and infections of the digestive and genito-urinary tracts are noticed in animals. They have also been clinically observed in man. Urinary calculi are common in experimental rats. In India, where stone is prevalent, McCarrison found that foods with vitamin A counteracted their formation. Toad skin is another symptom of vitamin A deficiency.

The epithelium at the junction of the teeth and gums in dogs was shown by May Mellanby to become overgrown and infected with micro-organisms (pyorrhœa). Vitamin A is necessary for the formation of dentine and enamel.

Lack of vitamin A causes degenerative changes in the spinal cord and the medullary sheaths of the sciatic nerves, and to disturbance of the œstral cycles and failure of ovulation. In puppies E. Mellanby has described bony overgrowth and deformity at the base of the skull, causing destruction of the divisions of the auditory nerve with production of deafness.

Hemeralopia or night blindness is specifically due to lack of vitamin A; visual purple is derived from axerophthol. This peculiarity forms a handy method, by means of the dark adaptation test, of examining individuals for their state of vitamin A nutrition. Harris and his colleagues have made a special study of this test, and point out that the technique must be carefully controlled. By night blindness tests 30 per cent. of children in an elementary school were deficient in vitamin A, and 39 out of 40 became normal after treatment. All children in a home where vitamin A was abundantly supplied were normal.

Vitamin D

The early work of E. Mellanby showed that the fats preventing rickets were the same fats as those containing vitamin A, which suggested that vitamin A was the antirachitic substance. There were, however, several differences. McCollum found that cod-liver oil, after aeration at a high temperature, was still antirachitic but not anti-xerophthalmic. The antirachitic substance was stable to heat, and distinct from vitamin A. McCollum called the antirachitic substance vitamin D. The existence of two vitamins in fats was confirmed from experiments with spinach; spinach was strongly growth-promoting and anti-xerophthalmic, but failed to prevent rickets. Spinach and green leaves contain vitamin A, but not vitamin D. Butter contains vitamin A, and very little vitamin D. Cod-liver oil contains vitamins A and D in large amounts. The irregular distribution explains the varied behaviour of fats.

Mellanby later investigated the rickets-producing effect of cereals in the diet. It was counteracted by vitamin D. The addition of calcium salts was also compensatory. The rachitic substance in cereals is phytin. Phytin has no toxic action, but forms an insoluble calcium salt and so removes it from solution; it has also an inhibiting action on the assimilation of calcium and phosphorus. The phosphorus of phytin is not available. Soluble phosphates are necessary in a low phosphorus diet. May Mellanby carried out parallel experiments on the teeth. Perfect teeth were produced with an ample supply of vitamin D in the diet. Decayed teeth were associated with too little vitamin D; and similarly, with cereals in the diet if the calcium, phosphorus, or vitamin D were too low.

The physiological action of vitamin D is to regulate the absorption of calcium and phosphate from the food in the intestine so as to maintain these elements at their proper and optimal level in the blood. In the diagnosis of rickets the estimation of calcium and of phosphate in the blood is of value. A better indication of incipient rickets, however, is the estimation of blood phosphatase, a high blood phosphatase being an early symptom of rickets.

The curative action of sunlight upon rickets was well known, and could not be explained by the existence of a vitamin. The demonstration by Huldschinski, in 1920, of the curative action of ultra-violet light from a mercury vapour lamp made possible the experimental study of the action

of light. Hume and Smith, at the Lister Institute, made the first observations leading to the explanation. Rats were kept in cages with sawdust as bedding. Some cages were exposed to ultra-violet light and others not so. Rats kept in the exposed cages did not get rickets, while the others did. The rats were seen to eat the sawdust. Light had produced in the sawdust an active substance having the effect of vitamin D. Next, foods known to be rachitic were exposed to ultra-violet light; they became antirachitic. The substance so activated was located in the fat, and traced to cholesterol and finally to an impurity in the cholesterol, later identified as ergosterol. Pure ergosterol from yeast on exposure to ultra-violet light is converted into active vitamin D. The new vitamin was isolated and called calciferol, and lettered D_2, as it was not proved to be the same as that in cod-liver oil. Two factors were thus needed in the prevention of rickets—the one ergosterol and the other ultra-violet light. Foods may contain the sterol or the activated sterol. The latter prevents rickets. The former is activated directly in the food, or indirectly after consumption in the fat under the skin. As a preventive measure against rickets the irradiation of foods is not altogether practicable. The food may become unpalatable and vitamin A is destroyed. Irradiated yeast is sometimes given to cows to improve the vitamin D value of their milk. Since calciferol has become a cheap commercial substance the best way of improving the vitamin D content of foods is by its direct addition in suitable quantity, as is carried out with dried milk and with margarine. Calciferol is available for medical use in various forms. Overdosage with calciferol must be avoided. The effect of high doses produces a big rise of calcium and phosphate in the blood, leading to abnormal deposits of calcium phosphate in the vascular system, spleen, kidneys, liver and lungs. The best method of securing vitamin D is in ordinary foodstuffs with the sterol which is activated later by sunlight.

The vitamin D content of foods is expressed in international units. The international unit of vitamin D is 1 mg. of olive oil containing 0·025 microgram of calciferol. One unit daily heals rickets in young rats in 8 days. Coward and Morgan have given the following figures per 100 grams: halibut-liver oil, average 257,000; cod-liver oil, 12,700; butter, average, 100 to 200; cream, 50; milk, 10 to 100; egg yolk, 150 to 400; canned salmon, 600 to 800 international units.

The daily requirement of vitamin D varies with the available sunlight, the amount of sterol in the food, and the proportions of calcium and phosphorus. The League of Nations Nutrition Committee recommends at least 150, and for full growth and vigour 400–500. L. J. Harris advises for infants 1500 units daily as preventive quantity, and 3500 as curative. A suitable supplement is 500 to 1000 units a day for a child or mother. A teaspoonful of cod-liver oil gives 300 units.

Vitamin D_2, or calciferol, is not identical with vitamin D in fish-liver oils. A sterol, 7-dehydrocholesterol, can be made from cholesterol by oxidation and activated by ultra-violet light into vitamin D_3, which is as active as vitamin D_2. The same substance has been isolated from fish liver oils, so it seems that vitamin D_3 and D are identical. Both D_2 and D_3 are equally active in preventing or curing rickets in rats and man; in chicks, however, vitamin D_3 is more active. The production of an active vitamin D from a sterol by ultra-violet light depends upon the structure of the sterol. Many

sterols have been examined, and several give active vitamins, D_4, D_5, etc. Many are present in various foods, and will serve as precursors of vitamin D. In skin the precursor is 7-dehydrocholesterol derived from fish in the food.

Vitamin E

The failure of rats to reproduce on a diet containing cod-liver oil (vitamins A and D) and yeast (vitamins B_1 and B_2), announced by Evans and Bishop in 1922 and corroborated many times, is due to the absence of another fat-soluble vitamin E. Rats do not need vitamin C. Vitamin E is found in the oil of lettuce and green leaves, and in the germ of whole cereals. Vitamin E has been isolated from wheat germ oil, identified and synthesised. Two varieties exist, known as α- and β-tocopherol. Vitamin E resists oxidation, but is destroyed by contact with rancid fats or with iron salts.

The failure of reproduction is "resorption gestation," *i.e.* death of the fœtus in the uterus and its resorption into the maternal organism. Females recover after giving wheat germ oil, but in males the germ cells degenerate and sterility is permanent. The ordinary human diet contains enough vitamin E, but an insufficiency may arise from diets having little green vegetable and too much white flour. Cases of habitual abortion in cattle, and a few cases of persistent miscarriage in women have been treated successfully with wheat germ oil. Other effects of vitamin-E deficiency are degeneration in the kidneys, discoloration of the uterus, muscular dystrophy, and alimentary exudative diathesis. Synthetic α-tocopherol prevents these symptoms.

Vitamin K

A deficiency disease characterised by subcutaneous and intramuscular hæmorrhages with delayed clotting of blood in chickens was described by Dam and Schonheyder, in 1934, and ascribed to lack of a fat-soluble thermostable vitamin K. Their results have been fully confirmed. Vitamin K is most abundant in hog's-liver fat, and green leaves. Two natural substances vitamins K_1 and K_2 have been isolated and identified as 2, 3-derivatives of 1, 4-naphthaquinone. The simple 2-methyl-1, 4-naphthaquinone has similar properties. Clinically, injections of emulsions of vitamin K have produced a reduction in the clotting time of the blood of patients with obstructive jaundice, and hæmorrhagic states in infancy have responded to treatment with the vitamin.

Vitamin B_1

Eijkmann's observations (1897) that fowls on a diet of white rice suffered from a peculiar form of paralysis called *polyneuritis gallinarum*, very similar to the symptoms of beriberi in man, and the cure of both birds and man on being given whole rice or rice bran, were the foundation of investigations on deficiency diseases. Whole cereals, pulses, and nuts were also found to be preventive, whereas white cereals led to the disease. The idea that a disease was due to the absence of some unknown substance from the food is due to Grijns (1901). The idea was strengthened by Fraser and Stanton's

extraction of the preventive substance by means of alcohol, and Funk's isolation of an impure substance, vitamine, which cured polyneuritis in pigeons.

The occurrence of beriberi amongst our troops in the Dardanelles and Mesopotamia during the War of 1914–1918 stimulated further investigations. Numerous foods were tested for their anti-beriberi value by Cooper, and by Chick and Hume at the Lister Institute using the pigeon as test animal. Their data on the cure and prevention of polyneuritis in pigeons were so similar to those on the growth of rats on foods tested for water-soluble B that these two unknowns seemed identical, but there were some differences to cause doubt. Another difference was in the stability to heat. The anti-beriberi vitamin is destroyed by high temperatures, especially in presence of alkalis, but the water soluble growth vitamin is stable. The Vitamin Committee of the Medical Research Council adopted the view of two different vitamins. They called the anti-beriberi vitamin B_1, and the growth-promoting vitamin B_2. The irregularities in distribution were due to differences in amount: yeast contains both equally; wheat germ has more B_1 than B_2; egg white has B_2, but not B_1; and meat has more B_2 than B_1. The comparative vitamin B_1 values of most common foods were examined by Plimmer, Rosedale, Raymond, and Lowndes, but in the absence of a definite standard at that time the data were quoted in terms of dried yeast as 100. Their figures correspond in most cases with the figures by newer methods in terms of the international standard. Vitamin B_1 is most abundant in dried yeast, yeast extracts, germ of cereals, pulses and nuts, with very little in leaves and fruits. Liver, heart, kidneys, egg yolk and cod's hard roe contain appreciable quantities, but lean flesh and fish flesh very little.

The estimation of vitamin B_1 in foods is by the bradycardia method, developed by Harris and Birch. The rate of the heart-beat of rats on a diet deficient in vitamin B_1 falls from about 550 to 300, and is rapidly restored on giving food containing vitamin B_1. The vitamin B_1 value of the food is estimated by determining the amount of the food which restores the heart-beat in comparison with a standard preparation made from rice bran or a standard quantity of pure vitamin B_1. Many foods have been analysed in this way by Baker and Wright. A newer purely chemical method, in which the vitamin B_1 is extracted and determined after oxidation to thiochrome is used by Pyke (1940).

Vitamin B_1 was isolated from rice bran and yeast, and its chemistry fully established. The pure synthetical vitamin, called aneurine or thiamine, is available for medical use and other purposes. Aneurine hydrochloride was adopted in 1938 as standard of measurement. Three micrograms corresponds with one international unit. The amounts of aneurine in some common foods in micrograms μg. per 100 grams are: dried yeast, average 9000; yeast extract, marmite, average 6000; wheat germ, bemax, average 3900; whole wheat, average 900; whole wheat bread, 360; brown breads, 150 to 420; white bread, 30 to 60; oatmeal, 300 to 510; lentils, 630; haricots, 360 to 480; fresh peas, 90 to 120; canned peas, 360; walnut, hazelnut, 450 to 600; vegetables, 30 to 210; fruits, 30 to 120; potato, 90 to 120; lean meats, 90 to 150; pork, ham, lean, 660 to 960; fish, 90 to 120; milk, 70; cheese, 0 to 90; liver, kidney, 450 to 570; egg yolk, 420.

Aneurine is closely connected with the metabolism of carbohydrate. In

the form of its pyrophosphoric ester it becomes co-carboxylase, which is concerned with the removal of pyruvic acid. In the absence, or with too little aneurine pyruvic acid accumulates in the blood, tissues and brain. The excess of pyruvic acid in the brain causes the head retraction, the symptom of polyneuritis, in birds, and is the cause of bradycardia. In man the heart beat increases in rate. The estimation of pyruvic acid in the blood is a possible means of detecting and confirming beriberi.

Aneurine is excreted in the urine. It can be adsorbed on kaolin and determined by the bradycardia method. A better method consists in adsorbing it, extracting with butyl alcohol and oxidising to thiochrome. Thiochrome shows a marked fluorescence in ultra-violet light according to quantity. Harris suggested the estimation of aneurine in urine to ascertain the level of nutrition of vitamin B_1. The resting level of the subject is determined and a test dose of 1050 μg. is given. In normals about 25 per cent. is immediately excreted as estimated 3 hours later. If less is excreted, the body is not saturated and the subject is on too low a level. The normal excretion varies according to diet from 50 to 170 μg. in 24 hours; 90 μg. is subnormal. On the reputed daily requirement of 900 μg. the output is 137 to 233 μg. On diets deficient in aneurine the output is 50 to 80 μg., in cases of beriberi almost 0. Women show lower values during and after pregnancy.

The requirement of vitamin B_1 by man depends on body weight and energy metabolism. The amounts of vitamin B_1 in diets leading to beriberi were calculated by Baker and Wright to be 450 to 750 μg.: a 10-stone man consuming 3000 calories requires 900 μg. daily to protect from beriberi; and a 14-stone man, 1125 μg. Other authors estimate a daily requirement of 900 to 2700 μg. The typical diet of white bread, butter, meat, sugar, and vegetables contains 600 to 1050 μg., and in the case of the poorer classes usually the smaller amounts. A large proportion of the population is consequently on a borderline diet. The effect of borderline diets, *i.e.* hypovitaminosis, can be judged from the numerous experiments on birds and rats. With very little, the animals soon die with typical symptoms; with larger but still insufficient amounts, life is longer; with still more, the animals live longer and die without showing the typical symptoms. Post-mortem examination shows enlarged heart, and intestines full of undigested food. McCarrison found these symptoms in the early stages of beriberi. The chronic enlarged heart and dropsical tissues were considered to be due to too little vitamin B_1. M. J. Rowlands particularly studied the effects of too little vitamin B_1 on rats. He observed distension of the stomach and visceroptosis, and a slower evacuation of the bowels. Resistance to infection was weakened, and bacteria entered the body through the degenerated mucous membranes of the intestinal walls and infected other parts of the body. Drummond, Baker, and Wright (1938), in continuation of Rowlands' work, found that rats had a shorter duration of life, smaller litters, and a greater incidence of gastro-intestinal lesions, especially ulcerations. Constipation, ulcers, and cardiac troubles may thus in many cases be attributed to diets low in vitamin B_1.

The nature and functions of vitamins B_3, B_4, and B_5 which are associated with vitamin B_1 are uncertain.

Vitamin B_2 Complex

Vitamin B_2 is composed of several factors, B_2, B_6, B_7 and at least one more, the filtrate factor or pantothenic acid. The main medical interest of the vitamin B_2 complex is in B_7 or nicotinic acid, which cures the chief symptoms of pellagra. Adermin, B_6, and riboflavin, B_2 are also required.

Generally, but not invariably, associated with a maize diet, pellagra occurs in parts of S.E. Europe, Egypt, and in southern districts of U.S.A. It was first described by Pedro Casals in 1707 under the name of *mal de la rosa*, and attributed by him to a poor diet. Goldberger in U.S.A. eliminated the disease in parts of U.S.A. with an increase of animal foodstuffs. Hence pellagra was attributed to lack of animal protein, or more specifically to absence of one or more amino acids not present in the proteins of maize. Experimental work did not support this idea. As dried yeast, beef, liver, salmon were highly curative but not casein, Goldberger concluded that there was a special pellagra preventing or PP factor. Its distribution in foods was so similar to that of water soluble B, or vitamin B_2, that he thought the two were identical, especially as rats on a synthetic diet containing a preparation of B_1 suffered from a dermatitis seemingly analogous to the dermatitis of pellagra. The substance flavin, or lactoflavin, or more correctly riboflavin, was next isolated from egg white, milk and liver. It cured the rat dermatitis. Pure synthetical riboflavin, however, did not have the same result, and so it was assumed that an impurity, B_6, in the isolated riboflavin was the curative vitamin. Preparations of vitamin B_6, free from riboflavin, cured the dermatitis, but the animals failed to grow. Growth was restored with riboflavin. For rats the two vitamins are thus essential. Rats on a pellagra producing diet of maize and other cereals do not experience the dermatitis. The cereals contain vitamin B_6. Vitamin B_6 is not the PP factor, and rat dermatitis is not analogous to pellagrous lesions in man. Rats are not suitable animals for the study of pellagra. Vitamin B_6 was subsequently isolated and synthesised, and called adermin.

It was known that dogs on a pellagra-producing diet suffered from sore mouth and tongue—" black tongue "—and were cured by diets with yeast, beef, liver, etc. One of the best curative materials of both black tongue and pellagra is liver extract. Elvehjem (1937) isolated from liver extract a substance resembling nicotinic acid. On testing pure nicotinic acid on dogs with black tongue, they were cured. Four cases of pellagra were treated by Fonte *et al.*, and were cured, and later eleven cases were cured by Spies *et al.* with intravenous injections of 30 to 100 mg. daily. Doses of 50 to 1000 mg. have been given to man without harm, but large doses give a sensation of heat with flushing of the face, chest and back and tingling of the skin. Martin, Chick *et al.* found that pigs on a pellagra-producing diet suffered from lesions similar to pellagrous lesions in man, and again nicotinic acid was curative. Rats differ from man, dog, pig and monkey in not requiring nicotinic acid, but all need riboflavin and adermin. In man not all the symptoms of pellagra are cured by nicotinic acid. The absence of riboflavin leads to scaliness and inflammation of the lips, and cracks at the corners of the mouth—" angular stomatitis." Chick, Macrae and Worden have discovered that rats on a prolonged deficiency of adermin suffer from epileptic fits, also previously observed in pigs. For the prevention of

pellagra nicotinic acid, riboflavin and adermin are essential, though the significance of adermin is not clear.

Harris and Raymond devised a method of estimating nicotinic acid applicable to urine and have used it to determine the level of nutrition of this vitamin. The average excretion is 4 to 5 mg. a day. It is higher on diets with more nicotinic acid, such as yeast extract, and the output varies with the intake. In animals with a deficiency of nicotinic acid the output sinks almost to 0.

Vitamin C

In the Middle Ages it was recognised that fresh fruits and vegetables cured and also prevented scurvy, that dried fruits and vegetables had no effect, and that among fruits the orange and lemon were the best anti-scorbutics. A daily ration of not less than 1 oz. of lemon juice was used to prevent scurvy in the Navy; this quantity is man's minimal daily re-requirement.

Holst and Frölich's discovery that the guinea-pig on a diet without fresh fruit or vegetable suffered from scurvy made it possible to compare the antiscorbutic values of fruits and vegetables. These tests, first made by Chick and Hume in 1914–1918 for Army use, were extended to ascertain the effect of cooking and the addition of soda and of citrate to milk. Fruits and vegetables vary considerably in antiscorbutic value. Orange, lemon, tomato, and cabbage have a high value; grapes, beetroot, and turnip a low one. These findings became of practical use in feeding infants to prevent infantile scurvy. Orange or swede juice is given instead of grape juice.

Cooking is destructive of vitamin C; rapid cooking being less harmful than long slow cooking. The heating of vegetables a second time destroys the vitamin. Cooking with soda is destructive, as also is bicarbonate and the use of citrate with milk. Vitamin C is very sensitive to heat in the presence of air, and still more so with alkali. There is, however, little or no destruction of vitamin C in the canning of fruits and vegetables by modern methods in the absence of air. Jams and marmalade produced by long boiling do not contain vitamin C. Condensed and dried milk made by processes in which air is excluded retain their vitamin C value. Milk is low in vitamin C. Orange juice can be similarly concentrated and combined with dried milk. A most important source of vitamin C is sprouted peas, beans and grains of wheat or oats. Sprouted seeds are very valuable when fresh fruits and vegetables are scarce, and on long expeditions far from a base, though in these cases synthetical ascorbic acid is now taken.

Vitamin C was isolated from lemon juice by Waugh and King, and found to be identical with a hexuronic acid obtained from suprarenal gland by Szent-Gyorgyi. The best natural source is fresh paprika. Its chemistry is established, and the synthetical product is known as ascorbic acid or cevitamic acid.

Ascorbic acid is a reducing agent, and decolorises 2, 6-dichlorophenol-indophenol. This reaction, discovered by Tillmanns, was employed to distinguish lemon and fresh fruit juices from artificial and boiled juices. This reducing property has become (under properly controlled conditions) the standard method of estimating ascorbic acid in fruits and vegetables. The amounts of ascorbic acid in mg. per 100 grams in some common fruits

and vegetables are: orange and lemon juice, 60; apple, 3; banana, 15: grapes, 3; cabbage, 100; spinach, 40; potato, new, 20; old, 8; lettuce, 5; human milk, 6; cows' milk, 2.

Vitamin C or ascorbic acid is excreted in the urine, and is estimated in acid solution by the reduction of 2, 6-dichlorophenolindophenol. The daily excretion varies from 15 to 30 (mean 20) mg. on a diet with plenty of fruit and vegetable, and from 5 to 11 mg. on diets with little antiscorbutic food. Many of the body tissues contain considerable quantities of ascorbic acid, especially the suprarenal, intestinal mucosa, liver and eye lens. In scurvy in guinea pigs these organs have little or even none. Harris and Ray devised the saturation test for assessing the level of nutrition of the individual. The test consists in feeding a large dose, 700 mg. or more, of ascorbic acid as such or as orange juice and ascertaining if the output rises above that previous to the dose. If there is no rise, the body is unsaturated, but if 50 per cent. of the dose is excreted in 24 hours the body is saturated. A considerable number of people so tested were unsaturated. A simpler but less reliable test which serves as a guide is Gothlin's capillary resistance test. A pressure band is applied above the elbow. Bending the elbow produces increased pressure, and minute hæmorrhages appear if the capillaries are weak. Many children tested in Sweden had a low antiscorbutic intake, and improved on being given more. Ascorbic acid can also be estimated in blood: 0·7 mg. in 100 ml. is normal; 0·4 to 0·69 is subnormal.

Man's minimal requirement of ascorbic acid to prevent scurvy is 1 oz. of lemon juice, or 20 mg. ascorbic acid. Höjer found that the teeth of guinea pigs rapidly degenerated with too little vitamin C, and that at least twice the minimal quantity was needed for prevention. Man would thus require 40 mg. Saturation tests have shown that 60 to 70 mg. are daily required. Babies are said to require 10 mg. daily. It is easier to give the figures as 1 mg. per kilo for man and woman; and 2 mg. per kilo for babies, pregnant and nursing mothers, and preferably also for older children.

A marked drop in the urinary excretion of ascorbic acid is observed at times of influenza or feverish cold. Patients with acute rheumatism, or tuberculosis, or osteomyelitis, or rheumatoid arthritis excrete less than non-infected control subjects. Such patients are in a state of lower saturation. In infections there is increased use or destruction of ascorbic acid in the body. There is no connection between ascorbic acid and antitoxin formation, but a connection has been traced with complement. The special action of ascorbic acid is, according to Wolbach, the production and maintenance of intercellular material, cementing the individual cells into a tissue. This explains the weakness of the blood vessels allowing hæmorrhages, and the lack of tone in skeletal muscles. The general disintegration of the tissues begins before the appearance of pain and the acute symptoms of scurvy.

Vitamin P

It has been supposed that the fragility and permeability of the capillary walls to plasma proteins is due to a separate vitamin P, but this has not been verified and is the result of too little ascorbic acid.

R. H. A. Plimmer.

SCURVY (SCORBUTUS)

Scurvy belongs to the group of "deficiency" diseases, being due to the absence from the diet of a sufficiency of a specific "accessory food factor" or vitamin. It consists in a general disorder of nutrition, characterised by debility, mental apathy, anæmia, sponginess of the gums, ulceration of the mouth, and a tendency to hæmorrhage.

Ætiology.—The theories, long entertained, that scurvy is the result of poisoning by a ptomaine or of a deficiency of potassium salts or alkaline compounds in the blood, have now been abandoned, and it has been abundantly proved by the experimental work of Holst and Fröhlich and their successors that the disease results from a deficient intake of the anti-scorbutic vitamin C (ascorbic acid) (see Vitamins, p. 449). Bad hygienic conditions appear to favour a development of the disease; but as a rule it seems to require an exposure of from 4 to 8 months to scorbutic conditions before it appears.

Pathology.—The pathological changes are: (1) An increased permeability of the capillaries to the red cells. This is responsible for hæmorrhages into the skin, subcutaneous tissues, under the periosteum, into the joints, and sometimes into the pleura and pericardium. (2) An interference with the normal growth of the erythrocytes. This produces an anæmia, which is usually orthochromic and normocytic, but may be microcytic and, on rare occasion, macrocytic. (3) A change in the bone, the result of unorganised provisional bone, which occupies a wide area at the growing ends of the bones. This bone is very friable.

Symptoms.—Scurvy is a disease of insidious onset. The earliest symptoms are weakness and lassitude, dizziness on standing up, and bruising or bleeding from the gums on slight provocation. Pains in the lower limbs are often complained of, and there may be a characteristic hardness of the calf muscles. Follicular keratosis is an early sign (Wiltshire), and in appearance is similar to the hyperkeratosis of follicles met with in other malnutritional states. Meanwhile the patient looks ill. The face becomes sallow and drawn, and the eyes lustreless and encircled by dark rings.

Such symptoms may precede by a few days, or even weeks, the more characteristic signs. Among these the most striking, though not necessarily always present, are the changes in the mouth. The gums begin to swell, especially around stumps or carious teeth, and as the process goes on the swelling may become so great as to amount to a veritable hypertrophy, so that the teeth become buried in a mass of soft fungous tissue of a bluish or purplish tint. Ulceration quickly follows along the margins, the process being accompanied by the discharge of a sanious fluid which imparts great fetor to the breath. Finally, the teeth become loosened in their sockets and may fall out, while necrosis of the alveolar edges ensues.

Equally characteristic and constant are hæmorrhages into the skin and subcutaneous tissue, which assume the form either of petechiæ or of ecchymoses. The former occur as small red or purple spots resembling flea bites, which appear first around the hair follicles of the lower extremities, and impart, by the elevations which they produce, a slight feeling of roughness to

the skin. They remain for about a week, and then gradually fade into greenish spots, which soon disappear; their disappearance being followed by a slight degree of desquamation. The production of the petechiæ is determined by the slight irritation caused by the friction of the clothes, and hence they are always to be found first on the outer surface of the leg, and the outer and anterior aspects of the thigh. Here and there the petechiæ may coalesce into larger areas or maculæ. In severe cases the slightest pressure on the skin is sufficient to cause ulceration, the ulcers having thick edges and bleeding surfaces with offensive discharge. Such ulcers may spread rapidly and invade surrounding tissues, giving rise in some cases to dangerous, and even fatal hæmorrhage. Ecchymoses, the other characteristic surface lesion of scurvy, are produced by hæmorrhage into the subcutaneous or intermuscular tissue. They may occur spontaneously or as the result of injury, and vary greatly both in size and extent, being commonest in the lower extremities, where they may form quite large swellings. The part affected by them is brawny, tender, and pits on pressure, the indentation persisting longer than it does in ordinary œdema. The skin over them is red, shiny and hot. Such effusions are common, also, in the popliteal space and in the bend of the elbow, as well as in the loose tissue around the malleoli, and beneath the muscles of the jaw. In these situations they form indurated swellings which fill up the natural hollows of the part, and greatly interfere with the movements of the adjacent joint. Where such effusions occur over the shins they are apt to be mistaken for syphilitic nodes. There is no marked tendency to bleeding from the internal organs; but hæmorrhages may take place from the mucous surfaces. Of such hæmorrhages, epistaxis and bleeding from the mucous membrane of the mouth are commonest. Bleeding may also occur from the mucous membrane of the intestine when there is a coexisting diarrhœa. Hæmoptysis, hæmatemesis and hæmaturia are rare. Hæmorrhagic effusion into the pleura and pericardium has also been described. Not uncommonly hæmorrhage occurs under the conjunctiva, and may be so extensive as appreciably to raise the ocular layer, leaving the cornea at the bottom of a pit surrounded by swollen and red conjunctival membrane.

As the disease progresses anæmia becomes a marked feature, though its degree has no constant relation to the extent of the ecchymoses. The blood picture is that of a secondary anæmia, the red cells being sometimes reduced to 2 millions per c.mm, or less. Poikilocytosis and anisocytosis are common, nucleated forms rare. The hæmoglobin is reduced roughly in proportion to the red cells, but the colour index may be less than 1·0 and on rare occasions over 1·0. Observers differ as to the white cell count. Some have described a leucopenia; others a moderate lymphocytosis. All are agreed that polynuclear leucocytosis is not present unless inflammatory complications coexist. Apparently the coagulability of the blood is not diminished, and the serum is not hæmolytic; but although the presence of a diminished alkalinity has been alleged our knowledge of the chemical changes in the blood is still limited.

Alimentary symptoms may be absent. Appetite is not necessarily impaired; but dyspepsia may be present, as the result of the dietetic conditions which produce the disease. Constipation is the rule; but the conditions in which scurvy develops often favour the production of a

dyspeptic type of diarrhœa with sanguineous discharge. The urine may be albuminous.

Complications—Gangrene of the lung is one of the most frequent and dangerous of the complications. Bronchitis and bronchiolitis also occur. Night blindness is met with not unfrequently, and is due to an associated deficiency of vitamin A.

Diagnosis.—If all the characteristic symptoms are present, and if the disease arises simultaneously in a number of subjects in circumstances known to favour its development, the diagnosis is easy. Difficulty only occurs when one has to deal with sporadic cases, such as those of land-scurvy, met with in ill-fed individuals.

The disease which perhaps most closely resembles it is purpura hæmorrhagica (morbus maculosus of Werlhof); but in this the affection of the gums is absent, and the hæmorrhages have not, as they have in scurvy, an inflammatory character. Mercurial cachexia, which in many points closely simulates scurvy, is now but rarely seen, and an inquiry into the history will usually lead to a correct conclusion. Acute lymphatic leukæmia, which is so often marked by ulceration in the mouth, can be distinguished by an examination of the blood.

Prognosis.—This, except in the severest cases, is favourable, provided that proper treatment is adopted. The outlook depends less upon the severity of the local lesions than upon the condition of the internal organs, and the presence or absence of complications. Extensive bronchitis or severe diarrhœa is of grave omen, and gangrene of the lung nearly always proves fatal. Even in uncomplicated cases, sudden death may be brought about by severe hæmorrhage or heart failure. In the most favourable circumstances convalescence is apt to be protracted, and when recovery is otherwise complete there may still be results left behind in the shape of cicatrices in the skin or partly anchylosed joints.

Treatment.—Prophylaxis consists of a diet containing from 25–50 mg. of ascorbic acid (500–1000 international units), for this will prevent scurvy. (For details see p. 449.)

If the disease develops, a sufficiency of ascorbic acid should be administered at once. This can be given either as pure ascorbic acid, or in the form of the juice of a lemon, orange, or of grapefruit, or blackcurrants, all of which are rich in ascorbic acid. The patient will recover most quickly if 1000 mg. of pure ascorbic acid is prescribed daily for 3 to 5 days. After this, at least 100 mg. of ascorbic acid should be given in the form of orange juice until complete recovery has occurred. It is usually unnecessary to administer iron, since the anæmia recovers rapidly, but it is advisable to prescribe an adequate amount of the other vitamins, because the patient may also be suffering from a lack of these. Local treatment for the gums is advisable, the teeth should be scaled, and the gums sponged with hydrogen peroxide.

The Sub-Scurvy State

Recent work has shown that many people are in what is termed the sub-scurvy state as the result of diets containing very little ascorbic acid. The symptoms are latent until an individual is wounded or operated on. Then the wounds heal very slowly and the operation wounds are apt to break

open. Again, ulcers are liable to bleed. In such cases the diet should always be considered, and if found to be unsatisfactory, 2000–3000 mg. of ascorbic acid should be given. In cases of pyloric stenosis 300 mg. should be administered intravenously for 3 days prior to operation, and the usual dose immediately after it.

ROBERT HUTCHISON.
GEORGE GRAHAM.

INFANTILE SCURVY

Infantile scurvy—known on the Continent as Barlow's disease—is identical in its pathology with the adult form of the disease, its special clinical features being due to the anatomical and physiological peculiarities of early life.

Ætiology.—The disease usually appears between the eighth and twelfth months — both sexes being equally affected. As in adult scurvy, the essential cause is the absence from the dietary of a sufficiency of anti-scorbutic vitamin. Any heating of milk reduces the amount of vitamin C present. Certain commercial processes in condensing or drying milk may completely destroy the vitamin. Pasteurisation is the least harmful process. In any case the addition of vitamin C to the diet is so easy that it is better to make milk a safe food by some heating process rather than to rely on it as a source of anti-scorbutic vitamin. A few cases have been recorded in which the child had been fed on the breast only ; it is probable that in these the mother's diet had been deficient in fresh constituents.

Pathology.—The chief changes are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hyper-vascular, thickened and separated from the subjacent bone by a layer of partially organised blood clot. There is no sign of inflammation, and no hard bone is formed in the periosteum, except in very long-standing cases ; in which circumstances the muscles surrounding the bone may be infiltrated with blood or serum, and look sodden. The bone exhibits rarefaction, and may be fractured. There may be hæmorrhagic effusions into the joints or serous cavities. The organs exhibit no characteristic change.

Symptoms.—The onset is gradual, the first symptoms noticed being often a refusal of food, along with fretfulness and restlessness. There is a tendency for the child to resent being handled. Meanwhile the general nutrition is usually unimpaired, and the child's colour is often fresh and healthy looking. After a variable period the more prominent symptoms appear. The most striking of these is extreme tenderness of the legs, which causes the child to scream loudly when touched or even when approached. In a well-marked case some swelling will be found, usually of the lower end of the femur or upper end of the tibia. Involvement of the arm bones is much rarer. The skin over the swelling is often tense and glossy, and may be slightly œdematous ; but there is no local heat. Soft crepitus may be elicited on handling the limb, indicating a fracture or a separation of the epiphysis. In some cases hæmorrhage takes place into the orbit, giving rise to proptosis and ecchymosis of the eyelid. Rarer sites of hæmorrhage are around the ribs, clavicles or bones of the skull.

Changes in the gums are not nearly so pronounced as in adult scurvy, and are not usually present, unless some teeth have been cut; in that case the gum around them is usually swollen and of a purplish colour. Petechiæ and subcutaneous ecchymoses are very rare in infantile scurvy, and hæmorrhage from mucous membranes is not common. Hæmaturia, however, is not infrequent, and red blood cells, in microscopical examination, are nearly always present. Fever is not a conspicuous feature, but may be present if extensive hæmorrhages have taken place; it rarely exceeds 102° F. The blood changes are the same as have been described in the adult form of the disease.

Diagnosis.—This is easy in a well-marked case, provided the leading features of the disease are known to the observer. The screaming of the child on examination, the swelling and tenderness of the legs, and the condition of the gums leave no doubt as to the nature of the affection with which one has to deal. All cases, however, are not so pronounced in type. Not infrequently one encounters mild or incipient forms which it is easy to overlook. In these, tenderness when the child is handled, or when it is put in the bath, may be the only symptom. In other cases again, slight sponginess around the incisor teeth may also be present, or one may have to deal with an apparently causeless hæmaturia. In any case in which there is doubt two points will help. One is the nature of the feeding. If this has been of such a kind as is known to favour the development of the disease the diagnosis will be greatly strengthened. The other point is the application of the therapeutic test. If the symptoms present are really due to incipient scurvy then they will certainly disappear rapidly so soon as appropriate treatment is begun; if they fail to do this, then some other condition must be thought of.

Infantile scurvy may be mistaken for rheumatism, although the mistake should not occur if it be remembered that acute rheumatism is hardly ever seen below the age of 2. The distinction between scurvy and suppurative periostitis or epiphysitis is much more difficult, especially if the gum changes are absent. A very high temperature and much constitutional disturbance are against scurvy. The nature of the diet will also be of weight in the diagnosis. A skiagram will be of great assistance in coming to a conclusion. In scurvy the shadow due to subperiosteal hæmorrhage, and a sharp dark epiphyseal line, are characteristic.

The absence of swelling in the affected limb and of the other symptoms of scurvy should distinguish those cases of infantile paralysis in which there is much tenderness of the paralysed leg, and the blood examination should enable one to differentiate a case of acute leukæmia or chloroma.

Prognosis.—This is quite favourable, provided the disease is recognised in time and proper treatment adopted. Nothing in therapeutics is more striking than the rapidity with which such patients improve on a change of diet, although some degree of thickening of the bones may persist for a long time. Death, when it occurs in the more severe cases, is usually the result of intercurrent disease, such as broncho-pneumonia and chronic diarrhœa, although sudden hæmorrhage, cardiac failure or exhaustion may occasionally lead to a fatal issue.

Treatment.—The first step is to bring the disease under control by administering vitamin C in concentrated form as ascorbic acid. This can be given in tablets by mouth, crushed just before use, in a dose of 50 to 100

mg. daily for 2 or 3 days for an infant of 9-10 months. During this period dietetic changes can be made, such as the introduction of orange juice or tomato juice, the institution of mixed feeding (baked potato is particularly valuable), and a change from any over-heated milk or milk product to plain milk just brought to the boil for safety. In very severe cases ascorbic acid can be given intravenously. Iron is useful if there is anæmia present.

Scorbutic infants should be handled carefully, and the clothing so made that it can be easily taken off and on. If it is necessary to move the child about it should be carried on a pillow. The affected limb should be steadied by light splints or wrapped in wet towels, which, if allowed to dry in position, afford considerable support. In mild cases a covering of cotton-wool secured by a light bandage is sufficient protection.

RICKETS

Definition.— Rickets is a disease of nutrition occurring in early childhood. It mainly affects the growth of the bones, but may be accompanied by tetany in some cases. Associated nutritional disorders produce anæmia and a tendency to catarrh of the mucous membranes in many instances.

Ætiology.—Various theories have been held in the past as to the cause of rickets, but it is now clear that it is essentially due to absence of vitamin D in sufficient amounts to promote adequate calcification of growing bones. The fault is usually dietetic and not only because of deficiency of vitamin D containing foods but also because excess of carbohydrate promotes more rapid growth than calcification can cope with. The ultra-violet rays of sunshine can manufacture vitamin D in the skin. Hence all those conditions which prevent the free access of unfiltered sunshine to the skin of the growing infant may be regarded as predisposing to rickets.

Pathology.—The chief changes are in the bones. Section through the end of a long bone shows that ossification, instead of proceeding in an orderly way, is greatly disorganised. In the zone of proliferation of the cartilage the cells show excessive multiplication, and are arranged irregularly instead of in columns. A broad bluish area results, which is the cause of the thickening of the epiphysis. In addition to this, calcification between the cells is defective, the affected area shows excessive vascularity, and the new bone formed is soft and deficient in lime. The whole process has been summed up in the statement that " there is an excessive preparation for ossification and a defective accomplishment of it." In addition, the vascular layer of the periosteum is thickened and the marrow congested.

Chemical analysis shows that the bones contain only from 30 per cent. to 50 per cent. of calcium, instead of the normal 60 per cent. or more. They may show signs of old or recent fracture. Other organs show no characteristic change.

Symptoms.—The disease can rarely be recognised before the sixth month. Amongst the earliest indications to attract attention are restlessness and irritability, sweating about the head, especially when asleep, and a tendency on the part of the child to kick off the bedclothes at night. There is no wasting, indeed the infant may be abnormally fat, though usually flabby and pale. The appetite is capricious.

As the disease progresses, it will be found that dentition is delayed, and that changes in the bones become manifest. They first show themselves in the epiphyses of the ribs, which enlarge and form a row of knobs down the sides of the chest (the rickety rosary). Enlargement of the epiphyses of the bones of the limbs then takes place, being most conspicuous at the lower end of the radius.

The softening of the bones leads to various deformities. The chest sinks in at the line of junction of the ribs and cartilages, so that a broad groove forms, running downwards and outwards towards the axilla (Harrison's sulcus). The bones of the limbs bend, the femur curving forwards and outwards, and the tibia bending sharply forwards and often also outwards at its lower third; there may also be a curving of the upper part, leading to "bow-leg." The humerus and bones of the forearm may become bent in an outward direction, as the child sits supporting itself on the hands, and the clavicle may show a sharp kink at the junction of the inner and middle third. The pelvis becomes flattened. Greenstick fractures of the limb bones are not uncommon.

The skull shows striking changes. It is usually somewhat enlarged, elongated and flattened on the vertex (box head), the anterior fontanelle remaining widely open long after the normal period of closure at the eighteenth month. There may be pronounced thickening of the frontal and parietal eminences, leading to the so-called "hot-cross bun" or bossed head, especially in cases complicated by anæmia with enlarged spleen. Areas of defective ossification in the parietal and occipital bones in the neighbourhood of the occipital suture (cranio-tabes), which yield on pressure a characteristic parchment-like sensation, are not uncommon, especially in young infants, even before six months of age.

The muscles are often so weak and flabby that paralysis is simulated, and the ligaments may be so lax that the limbs can be bent into almost any position ("acrobatic rickets"). In consequence also of the laxity of ligaments, kyphosis often develops in the lower lumbar region (rickety spine).

The blood usually shows a varying degree of anæmia of the hypochromic type, and in a few cases the changes are so profound as to resemble those met with in chlorosis.

The digestive system is usually deranged. Chronic diarrhœa with pale, offensive stools is not uncommon. The abdomen is distended so that the child has a pot-bellied appearance. In the production of the distension, muscular weakness, intestinal fermentation, and the pushing down of the diaphragm by the sinking in of the chest all play a part. The edge of the liver can often be felt at a lower level than normal, partly from displacement and in part from enlargement through fatty change. The spleen is also palpable in a considerable number of cases, although this is due more to its being pushed down than to actual enlargement.

In the respiratory system bronchial catarrh is very often present, and not uncommonly results in broncho-pneumonia. In the nervous system the disease shows itself by general nervousness and irritability, and in some cases by the development of laryngismus stridulus, tetany, or even convulsions, of all of which rickets is a strong predisposing cause.

Diagnosis.—In a fully developed case the diagnosis is easy. Early cases, and those in which the rickety element is overshadowed by some

complication, such as broncho-pneumonia or diarrhœa, are more apt to be overlooked. The suggestive points will be delayed dentition, an open fontanelle, and the presence of the rickety rosary. A skiagram will show some cupping of the diaphysis; the epiphyseal line will be irregular and ill-defined, and the epiphysis itself poorly ossified. There will also be a tendency to osteoporosis throughout the whole bone. The appearance of the epiphyses of the carpus and tarsus may be retarded.

The rickety head is apt to simulate hydrocephalus, but in the latter condition the skull is more globular, and bulges above the ears, the fontanelle is tense, and the eyeballs, in marked cases at least, pushed downwards. The kyphosis of rickets may be mistaken for spinal caries; but in the former the bend straightens out as a rule when the child is held up by the armpits. In severe cases this may not happen, and a radiograph may be required to settle the diagnosis. If the muscular weakness is pronounced infantile paralysis may be imitated; but the history, the retention of the reflexes, and the presence of other signs of rickets should prevent mistakes.

Prognosis.—Rickets is not fatal *per se*, and usually passes off spontaneously after the second year, although the deformities of the bone may persist for a long time. Even these, however, have a wonderful way of righting themselves without any special treatment. On the other hand, rickets is a very serious complication of other diseases, especially of broncho-pneumonia and diarrhœa, and adds greatly to their fatality if present, so that the dictum of Sir William Jenner that "in its indirect results rickets is one of the most fatal diseases that peculiarly affect childhood" is still perhaps true.

Treatment.—Rickets can be prevented if the child is properly fed and cared for. Breast-feeding for the first 9 months is the best safeguard, provided that the mother's diet is satisfactory; but it must always be remembered that the disease is apt to develop in children who are kept *too long* on the breast. After weaning, the premature and excessive use of starchy foods must be avoided. Care should be taken that the diet contains an adequate amount of animal fat. Plenty of fresh air, sunlight and exercise are also important factors in prophylaxis. It is probable that all infants in temperate and cold climates require a daily supplement of cod-liver oil ($\frac{1}{2}$ to $1\frac{1}{2}$ teaspoonfuls) between six months and two years of age.

If the disease has already developed, the diet should be altered in accordance with the requirements indicated above, the most important point usually being to increase the allowance of cow's milk, which should not fall below $1\frac{1}{2}$ pints per diem during the second year of life. Yolk of egg is also a valuable food. Cod-liver oil and halibut-oil (or one of the artificial substitutes containing vitamin D) are most useful, having a specific influence on the disease; but iron may also be given with advantage if there is anæmia. It is wise to start with a pure vitamin D concentrate in adequate dosage for about a month to bring the disease under control. Sun-baths or exposure to the rays of the mercury-vapour lamp have a definitely curative effect.

To prevent bending of the legs, long splints may be applied, projecting beyond the feet, so as to make standing impossible. Orthopædic treatment may be required for the more permanent deformities. Alimentary and respiratory complications should be treated by the measures appropriate to them.

Late or Adolescent Rickets

This term is applied to a disease apparently identical with ordinary rickets in its bony changes, but which sets in much later, usually between the ninth and fourteenth years. The patient may have been the subject of ordinary rickets in earlier childhood—hence the use of the term "recrudescent rickets"—or the disease may have appeared at the later age for the first time. Nothing is known of its causation, but in some cases it is associated with fibrosis of the kidneys (renal rickets) or with cœliac disease.

The manifestations of the disease are practically confined to the skeleton, the long bones being particularly affected. The epiphyses become much enlarged, and pronounced deformities ensue as the result of bending. The skull escapes almost entirely, and there is no tendency to any disease of the internal organs, except in the renal cases, or to complications.

The disease is not dangerous to life; but the deformities may be lasting. The general treatment is the same as that of ordinary rickets; but most cases will require the help of the orthopædic surgeon.

"Fœtal" and "congenital" rickets are ambiguous terms which have been loosely used to cover several distinct pathological conditions, amongst which are achondroplasia, mollities ossium, and osteogenesis imperfecta. They are best avoided. So-called "scurvy-rickets" and "acute rickets" are identical with infantile scurvy, although rickets often coexists with the latter, seeing that both are due to faulty feeding.

Alan Moncrieff.

BERIBERI

Synonyms.—Polyneuritis Endemica; Hydrops Asthmaticus; Kakke; Barbiers.

Definition.—A dietetic disease or group of diseases especially related to deficiency in vitamin B_1, occurring frequently in tropical regions where polished rice constitutes the main article of dietary. It is characterised by neuritis of the peripheral nerves and vagus. Several different clinical types are described.

Ætiology.—The rice-eating populations of India, Japan, Malaya, the Dutch East Indies and Philippine Islands are mainly affected, but the disease is also endemic in Newfoundland and Labrador, where the population eat chiefly white wheaten flour. Though the disease is specially rife amongst people eating polished rice, rice *per se* is not essential, any dietary deficient in the antineuritic vitamin B_1 being a potential source of danger. Parboiled and undermilled or husked rice are not deficient in vitamin B_1. During milling the husk, pericarp and germ, which are rich in protein, fat, phosphorus and vitamin B_1 (see p. 445) are removed, leaving the white polished rice poor in these constituents. Milled rice, white flour, breakfast cereals, macaroni, spaghetti and cane sugar contain practically no vitamin B_1. This vitamin, known also as "aneurine" or "thiamine," was synthesised in 1937 in crystalline form (1 mg. = 300 international units), and is now available

for therapeutical purposes. It is mainly found in yeast, marmite, whole seeds, the germ of cereals, pulses and nuts. Aneurine is a precursor of cocarboxylase, which removes, by oxidation, an important intermediary product of carbohydrate metabolism—pyruvic acid—from the tissues and blood. The chemical tests for the estimation of pyruvic acid and aneurine are dealt with on p. 447. Excess of pyruvate can be demonstrated in the blood in beriberi, the value rising from a normal of 0·4–0·6 mg. to 1–7 mg. per 100 c.c. The quantity normally present in the cerebrospinal fluid is also increased. When no complicating factor is present, 5 mg. of vitamin B_1 will restore the blood to a normal value in 10 to 15 hours.

Pathology.—Cases of so-called " dry beriberi " rarely come to autopsy. In " wet beriberi " there is an acute congestion of the mucosa of the duodenum and lower end of the stomach, sometimes associated with pin-point hæmorrhages. The peripheral nerves show a Wallerian degeneration, with possibly an axonal degeneration of the neuron involved. The sheath of Schwann may exhibit multiplication of its nuclei and invasion by leucocytes. The vagus and sympathetic system may present stigmata of degeneration, and sometimes the anterior-horn cells of the spinal cord and the nuclear connections of the vagus in the floor of the fourth ventricle are said to be implicated. The cardiac muscle may show œdema and degenerative changes, while the naked eye appearances are those of fatty degeneration associated with dilatation and hypertrophy, especially involving the right side. Nutmeg-liver, œdema of the soft tissues and effusions into the serous cavities are common. Adrenal hypertrophy, similar to that described by McCarrison in avian polyneuritis, has been recorded in man. In experimental animals the process underlying the nervous manifestations is a dysfunction and non-inflammatory; it has in consequence been suggested that the term " neuropathy " is more accurate than " polyneuritis." In long-term deficiency, however, damage to tissues may ensue which cannot be repaired merely by correcting the vitamin deficiency.

Symptoms.—There is generally a latent period of some two to three months before deficiency symptoms become manifest. Typically the onset is gradual, being characterised in the initial stages by epigastric discomfort, nausea and perhaps vomiting and diarrhœa. Later, polyneuritis, with palpitation, shortness of breath and weakness develop, the subsequent clinical picture varying according to involvement of the peripheral nerves, the vagus, or the sympathetics. The disease runs an afebrile course, except possibly in its early stages. Several different types are described:

(1) Larval or Ambulatory Cases.—There is numbness of the legs with patchy anæsthesia and diminution of knee-jerks, all of which quickly disappear if the condition is recognised and a more varied diet containing vitamin B_1 be given.

(2) Ordinary Beriberi.—(*a*) *Wet form.*—Prodromata include paræsthesias and heaviness of the limbs. The knee-jerks are at first exaggerated and then lost. Tenderness of the calf muscles, blunting of sensation, and patches of hyperæsthesia and anæsthesia appear. The patient becomes weak, and cannot rise from the squatting position. Varying grades of œdema, at first involving the subcutaneous tissues over the tibiæ, appear and, later, effusions into the serous cavities with water-logging may develop. Shortness of breath, dyspnœa and tachycardia indicate involvement of the cardiac

nerves. There are manifestations of dilatation of the heart, especially the right side (see pp. 857 and 956). Several factors may contribute to the œdema: (1) intracellular œdema associated with failure of cell nutrition; (2) cardiac failure or an increased tension of the capillaries; (3) decreased plasma proteins; and (4) secondary renal insufficiency. When the nervous manifestations are slight and the patient can still do muscular work, œdema is more likely to develop. Sudden death may occur without clinical evidence of cardiac involvement. (*b*) *Dry form.*—This is similar to the above except that œdema is absent and the disease runs a more chronic course. The onset is insidious, gastro-intestinal disturbances may be absent, the dominant features being wasting and weakness of the muscles, associated perhaps with cardiac irritability. Wrist drop and the high-steppage gait may be present, but though the patient walks unsteadily there is no true ataxia or Rombergism. Clinically, the disease closely resembles alcoholic neuritis and that encountered in pellagra, both of which are now regarded as being due to a deficiency in B_1. Wet beriberi may develop at any time, but this is less likely if the neuropathy is sufficiently severe to keep the patient resting.

(3) Acute Fulminating Beriberi.—Cardiac symptoms may predominate from the onset, or suddenly supervene in either the wet or dry forms. Cardiac decompensation of the congestive variety (see p. 856) rapidly ensues. Alteration of the voice or aphonia resulting from pressure of the dilated right auricle on the recurrent laryngeal nerve has been reported. The diaphragm also may be paralysed. Owing to renal insufficiency there may be a scanty urine containing albumin and casts, and a high blood urea which falls as the output of urine increases with treatment. Death may supervene in a few hours to a few days.

(4) Infantile Beriberi.—This disease occurs especially in the Philippine Islands and Japan, where it is responsible for many deaths in breast-fed infants whose mothers are affected with latent or clinical beriberi. More than 50 per cent. of cases show symptoms between the third and fourth weeks of life. The disease occurs in both acute and chronic forms. In the latter gastro-intestinal features like anorexia, vomiting, diarrhœa or constipation occur, associated with wasting, pallor, œdema, mainly involving the face and extremities, dyspnœa, and other evidences of cardiac insufficiency. Aphonia is often striking, and loss of knee jerks is present in 75 per cent. of cases. In the acute form death may occur with great rapidity, the infant developing convulsive attacks, suffering severe pain and presenting cyanosis, dyspnœa and muscular rigidity.

(5) Other Clinical Types.—These include *ship's beriberi*, which is now rare amongst sailors, and *pellagroid beriberi*, in which there is a mixed deficiency, the skin and mucosa membrane lesions being cured with nicotinic acid and the neuritic manifestations with vitamin B_1. *Secondary beriberi* may be associated with (1) gastro-intestinal diseases leading to defective absorption of vitamin B_1, (2) chronic alcoholism, or (3) pregnancy, diabetes, febrile states, or diseases increasing metabolism which lead to a relative deficiency by increasing the demand for B_1.

Epidemic Dropsy, which is met with in India and other parts of the tropics, occurs in epidemics amongst rice eaters and is often classified as a type of beriberi. Gastro-intestinal features, especially diarrhœa, are common.

Some degree of fever is, however, generally present, progressive anæmia is frequent, a vascular mottling of the skin over the tibia and inner side of the thigh is not uncommon, as well as a tendency to hæmorrhages involving the mucous membranes. Clinical evidence of neuritis is not obvious; the knee jerks are generally normal, and cutaneous anæsthesia and deep hyperæsthesia of the muscles absent. Some hold it is due to toxic substances developed in degenerating or diseased rice; others that it is caused by poisons in mustard oil. Its relationship to nutritional œdema in which there is a lowering of plasma proteins, does not appear to have been adequately investigated. Though simulating wet beriberi in some respects, there are obvious clinical differences, and the disease is probably not a pure B_1 deficiency.

Diagnosis.—Wet beriberi has to be diagnosed from cardiac failure, nephritis and severe ancylostomiasis, while the dry form has to be differentiated from alcoholic and arsenical neuritis, tabes dorsalis and progressive muscular atrophy. The dietetic history is important, and multiple cases of neuritis, especially if associated with œdema, should always suggest beriberi. Vitamin B_1 is greatly decreased or practically absent from the urine in cases of beriberi, and this test (p. 447) may determine the diagnosis in doubtful cases. Volhard's diuresis test may also be helpful, since there is water retention in beriberi.

Prognosis.—This depends on the institution of appropriate treatment at a reasonably early stage of the disease. Aneurine promptly cures the early neurological manifestations of "dry" beriberi, and relieves many of the advanced cases. It improves the cardio-vascular disturbances in "wet" beriberi, and is often a life-saving measure in acute fulminating beriberi with cardiac failure, provided it be given intravenously in adequate dosage. If the patient survives the first two weeks and an adequate maintenance dosage of B_1 be continued, recovery is probable. Cases which return to their previous polished rice diet are liable to relapses and sooner or later die of the disease.

Treatment.—PROPHYLACTIC.—Prophylactic measures consist in providing a balanced dietary adequate in B_1, *i.e.* 1–2 mg. daily. In institutions where polished rice or white bread is the main article of dietary, under-milled or parboiled rice and whole-wheat flour should be substituted. The addition of cooking soda to vegetables should be avoided, since boiling in the presence of alkali destroys B_1, though heat alone does not.

CURATIVE.—Dietary is an all important factor in recovery, and the introduction of crystalline vitamin B_1 (aneurine) has revolutionised treatment. In moderate cases 5 mg. of aneurine hydrochloride (thiamine hydrochloride, U.S.P.) should be administered daily in tablet form, but in acute fulminating beriberi intravenous injections are essential. Initially, injections of from 5 to 50 mg. may be necessary in severe cardiac cases, followed by daily injection of 5 mg. until symptoms are well controlled; subsequently, the aneurine can be given orally. Careful nursing and absolute rest in bed are necessary, and where there is cardiac failure small feeds containing marmite are given 2 hourly; later, a dry, low carbohydrate diet rich in vitamin B_1 and containing such articles as yeast, marmite, oatmeal, lentils, haricot beans, meat, eggs, liver, ham and heart muscle is advisable. Milk, butter and cream should also be included but rice is contraindicated. If there is

right-sided cardiac failure venesection is of great value. In infantile beriberi, artificial should be substituted for natural feeding or a healthy wet-nurse employed. Extract of rice polishings have proved effective therapeutically, in 2-hourly feeds, and toddy made from coconut milk fermented by yeast has been used with great benefit in certain Pacific Islands. Vitamin B_1 (aneurine hydrochloride) in adequate dosage should now be prescribed if available.

When there is polyneuritis, a cradle should be put over the feet and splinting may become necessary to prevent muscular contractures. After the acute symptoms have disappeared, massage and electricity to the limbs will help to restore the circulation and muscle tonus.

Mild cases of dry beriberi may be treated on a rice-free diet, low in carbohydrate and high in vitamin B_1; aneurine tablets in a dosage of 5 mg. daily should be given. Muscular work must be avoided as this is liable to precipitate wet beriberi.

When the plasma proteins are found to be low, intravenous serum or reconstituted plasma should assist in dispersing the œdema, as it does in the disease known as nutritional œdema.

PELLAGRA

Synonyms.—Mal de la Rosa; Mal del Sole; Maidismus; Malattia della Miseria; Asturian Leprosy; Alpine Scurvy.

Definition.—Pellagra is a chronic relapsing disease occurring especially in maize eaters, due to a deficiency in certain proteins and factors contained in the vitamin B_2 complex. Clinically, it is characterised by buccal and gastro-intestinal disturbances, psychical and nervous features, and a symmetrical eruption especially affecting areas of skin exposed to the sun's rays or to friction.

Ætiology.—Pellagra (pelle, the skin; agra, rough) prevails endemically in the Southern States of the U.S.A., lower Egypt, Turkey, Roumania, the Balkans, Spain and Italy, and has been reported from India, China, Japan, parts of Africa, Mexico, West Indian Islands, etc. People of any race, age or sex are susceptible, and the malady is more common amongst the poorer classes. The incidence of the disease is greater in the spring. It occurs particularly amongst maize eaters, and in poorer communities living on cereals containing a low protein content or protein of low biological value. Following the work of Elvehjem on canine black tongue, nicotinic acid (B_7) and its amide have been found to clear up the early dermal changes and mucous membrane lesions in pellagra and to relieve many symptoms referable to the central nervous system. Certain coenzymes contain nicotinic acid amide (Warburg and von Euler), and severely ill pellagrins usually have a low coenzyme content in the blood (Vilter and Spies). It has been suggested that an interference with general cellular metabolism may result from a deficiency of available respiratory enzymes. When infection or hyperthyroidism increase the oxidative activity of the body and when the enzymes which facilitate such activity are wanting owing to a deficiency of their precursors, a deficiency syndrome follows. Other factors in the B_2 complex, *i.e.* riboflavin (B_2) and adermin (B_6), as well as proteins, are also

Canine rays have some effect [illegible]

essential in preventing pellagra and probably have a closely inter-related function (see p. 448). Sporadic cases of true pellagra occur in alcoholics or are secondary to disease of the alimentary tract. They arise from mal-absorption of pellagra-preventing factors or from deficiencies in the dietary prescribed. Irrespective of whether the development of pellagra follows poverty, erroneous dietary habits, dietary idiosyncrasies, organic disease, chronic alcoholic addiction, or some combination of these factors, the lesions, symptoms and methods of treatment are essentially the same (Spies).

Pathology.—Emaciation is marked and the internal organs, including the heart and spleen, are small and atrophic. Skin lesions consist of an initial erythema involving the superficial layers, terminating later in a true exfoliative or exudative dermatitis. Stomatitis and glossitis with ulceration of the tongue, denudation of its epithelium and ultimate atrophy may ensue. The jejunum is congested and atrophic, and small round ulcers involving the jejuno-ileum, colon and rectum are described. The mesenteric glands may be enlarged. Demonstrable pathological changes in the nervous system are generally slight but there may be a subacute combined degeneration of the cord involving the posterior and lateral tracts, and especially Clarke's column (Wilson). Degeneration of the anterior-horn cells in the lumbar region, and subacute inflammation of the ganglion cells in the posterior roots are described, while Briauchi recorded meningeal thickening and adhesions, atrophy of the cerebrum, and hydrops of the ventricles and subarachnoid space. More than 50 per cent. of pellagrins show achlorhydria which is histamine-fast, but Castle's intrinsic factor appears to be secreted normally by the pyloric glands and megalocytic anæmia is rare. The total white count is generally normal in uncomplicated cases, there is often a lymphocytosis, and some degree of secondary anæmia is common. The cerebro-spinal fluid exhibits no abnormality.

Symptoms.—The exact incubation period is unknown, and it should be realised that prodromal symptoms may recur over long periods before the classical oral or dermal features develop. In this stage a definite history is most important in making a correct diagnosis. Generally there is a history of having lived for a long period on a diet high in fat and carbohydrate, and poor in proteins and vitamins, such articles as red meat, eggs, milk, fish, fresh vegetables and fruit being lacking.

Prodromal Symptoms.—These include anorexia, loss of weight and strength, dyspepsia, flatulence, vomiting, sensations of burning or discomfort in the epigastrium, constipation or diarrhœa, insomnia, headache, palpitation, vertigo, numbness, forgetfulness, nervousness, mental irritability and mental confusion. Later, characteristic involvement of skin, alimentary tract and nervous system may supervene, but all three systems are not necessarily affected in any one pellagrin, while the sequence and the severity of the symptoms show considerable variation in individual cases.

Alimentary features.—The glossitis and stomatitis which usually appear early in the disease are diagnostic. In the early stages the tip and sides of the tongue are red and swollen; later the whole organ becomes fiery red (beet tongue) and inflamed, with lateral indentations from the teeth. Deep ulcers may develop on the sides and tip, while the dorsum becomes covered with a thick grey membrane, containing Vincent's organisms. A similar condition may involve the buccal mucous membrane, palate, gums and the

muco-cutaneous surface of the lips. Hot, spiced and acid foods increase the ptyalism and the burning sensations felt in the tongue, pharynx, œsophagus and stomach. Other symptoms include nausea, vomiting and abdominal discomfort, flatulence and distension, especially after food. The bowels may act normally or be even constipated in the early stages, persistent diarrhœa being characteristic only of the advanced cases. In the latter the stools are non-fatty in type, diarrhœa occurs at all hours, and is often associated with colicky pain and tenderness. Sigmoidoscopy may reveal a proctitis. Associated vaginitis and urethritis are not uncommon.

Skin lesions.—Their distribution is on the back of the hands, wrists and forearms, the dorsum of the feet, the face, neck, upper part of the chest, under the breasts and in the perineal regions—in short, over those areas directly exposed to the sun's rays or friction. Commencing as an erythema resembling a severe sunburn, there is redness, swelling and tension of the skin, followed by itching, burning and possibly bleb formation, while later, a deeper dermatitis develops with desquamation and exfoliation. Pigmentation and thickening of the dermis result, but finally atrophy supervenes, the skin becoming wrinkled, inelastic and thinned. Pathognomonic features of pellagrous eruptions are their absolute symmetry and their sharply demarcated pigmented borders—the hyperkeratotic border of Merk.

Nervous system.—The early mental symptoms, which are often regarded as functional, include depression, apprehension, irritability, headache, insomnia, and bilateral burning sensations involving the extremities or other parts of the body. Later these mental symptoms are accompanied by rigidity, tremor of the tongue, coarse tremors of the limbs and head, athetoid movements and cramp; while numbness and paralysis of the extremities are common. The reflexes which at first are generally increased, later become decreased, and finally are often entirely absent. The gait may be spastic or ataxic, and cord involvement or peripheral neuritis due to associated B_1 deficiency may be factors in the production of the neurological picture. If improperly treated, insanity often results. Retardation of growth occurs in children, but fortunately neurological complications are not common in them.

The course of the disease is generally afebrile and characterised by definite attacks alternating with remissions extending over many years unless a proper diet be maintained.

Diagnosis.—In classical pellagra the glossitis, stomatitis and the characteristic skin lesions make the diagnosis easy, but these features occur only in the well-established disease and it is the subclinical cases or those presenting vague prodromal manifestations which are so important to recognise early. A reliable history of dietary deficiency is all important in this regard. The urinary test for nicotinic acid excretion devised by Harris and Raymond (p. 449) may clinch the diagnosis in doubtful cases. Pellagra sine pellagra may be confused with sprue or ergotism, while erythema multiforme and dermatitis venenata may cause difficulty (Stitt).

Prognosis.—In endemic pellagra if patients receive modern treatment and a maintenance diet adequate in vitamin B_2 complex and good biological protein, the mortality should be low. In the past, about 40 per cent. have been estimated to develop mental trouble, and many of these died in asylums. Fever is an unfavourable sign, and in the absence of intercurrent disease

occurs either as a terminal event or in the fulminating form known as typhoid pellagra, which is characterised by intense prostration, tremor, muscular rigidity, convulsions and death. In secondary pellagra, the prognosis depends on rectification of a faulty diet and treatment of the underlying alimentary trouble.

Treatment.—PROPHYLACTIC.—The addition to a pellagrin's diet of red meat, milk, eggs and substances rich in vitamin B_2 complex, *e.g.* brewer's yeast and marmite, will prevent the disease.

CURATIVE.—Rest in bed, a high calorie, nutritious diet low in carbohydrate but rich in protein, and foodstuffs containing vitamin B_2 complex are desirable. The diet should include fresh milk, lean scraped red meat, liver, canned salmon, tomato juice, fresh fruit and vegetables. Articles which have been found to possess curative value when given in large dosage include Brewer's yeast (75–100 g. daily), marmite (30–60 g. daily), wheat germ (250–300 g. daily), ventriculin (200 g. daily) and liver extract (75–100 g. daily). The discovery of the curative effects of adequate doses of nicotinic acid on many of the manifestations of pellagra has revolutionised the treatment of the disease. The drug is administered by the mouth, in tablet form and in divided doses, the daily dosage ranging from 200–1000 mg., 500 mg. being generally effective. After 10 days the dosage may be decreased. Flushing, burning and itching, nausea, vomiting and colic may follow, especially if the drug is given in large dosage on an empty stomach. Nicotinic acid also stimulates gastric activity and acid secretion, and is liable to elicit a mild histamine-like type of reaction. The mucous membrane lesions, including pellagrous glossitis, stomatitis, vaginitis, urethritis and proctitis, are healed and bowel function restored to normal, the early erythematous lesions are blanched, while the early and late mental relapse symptoms are greatly benefited. The chronic skin lesions, however, are not cured by nicotinic acid therapy. Associated symptoms of peripheral neuritis are not relieved by nicotinic acid, but both pain and numbness disappear after daily injections of 50–100 mg. of crystalline vitamin B_1 (Spies).

TROPICAL MACROCYTIC ANÆMIA

Synonyms.—Nutritional Macrocytic Anæmia; Tropical Megalocytic Anæmia.

Definition.—A severe nutritional anæmia, megalocytic in type, especially affecting pregnant women in the tropics and subtropics, and responding specifically to marmite or liver extract therapy. Non-hæmolytic and hæmolytic types are encountered.

Ætiology.—The disease affects both sexes but is especially common in women during the child-bearing period owing to the superadded nutritional demands of pregnancy and lactation; it develops during the latter half of pregnancy. It has been reported from India, China, Africa and Macedonia. The malady is found in rice-eaters in the southern half of India, where it affects all communities and grades of society (Wills). In Macedonia, it is prevalent in the refugee population, whose diet is poor in animal proteins and fat. Castle holds that lack of extrinsic factor in the diet is responsible, but Wills and Evans believe it is due to deficiency in a new hæmopoietic

factor contained in crude liver and autolysed yeast. The factor concerned has not been identified with any constituent of the vitamin B_2 complex. Most frequently the condition is associated with chronic malarial splenomegaly, which introduces a superadded hæmolytic factor through excessive phagocytosis of red cells by a hypertrophied and pathological reticulo-endothelial system resulting from repeated malarial infections over many years (Fairley).

Pathology.—In uncomplicated non-hæmolytic cases the organs are pale and may show fatty infiltration secondary to the anæmia. In fatal cases, there may be cardiac dilatation associated with fatty changes in the myocardium, a congested enlarged liver, œdema and other evidence of cardiac decompensation. Megaloblastic hyperplasia of the red marrow is found, and Ehrlich polychromatic megaloblasts are demonstrable in smears or sections. In cases of hæmolytic type associated with splenomegaly, there is, in addition, a generalised hypertrophy and hyperactivity of the reticulo-endothelial cells, which may contain malaria pigment and phagocytosed red cells, fine hæmosiderin deposits in the parenchyme cells of the liver and spleen, and a decrease of lymphoid tissue in the latter organ in which the Malpighian bodies may have disappeared. Hæmorrhages may be found in the skin and serous or mucous membranes. The bone marrow shows general hyperplasia of the myeloid cells, with increase in the activity and numbers of hæmocytoblasts and erythroblasts. Basophilic and polychromatic megaloblasts are common, but ripening sufficient to produce a really pink cytoplasm in a cell with a finely stippled primitive nucleus is a rarity. Pathological changes in the precursors of the white cell series are common, and megakaryocytes are liable to be atypical or scanty.

The condition is one of panmyelopathy in which some more primitive cell type than the megaloblast must be implicated. The reticulo-endothelium lining the marrow sinusoids is the ultimate source of erythrocytes, leucocytes and platelets, and it appears not improbable that the deficiency factor no less than malaria itself is exerting its deleterious influences on primitive reticulo-endothelium.

Symptoms.—In the uncomplicated *non-hæmolytic type* the symptoms are essentially those associated with a grave anæmia. The patient often first seeks advice for cardiac palpitations, giddiness, shortness of breath, weakness on walking and physical fatigue. Sore tongue, anorexia, vomiting, flatulence, abdominal distension and diarrhœa may be complained of, and fever or cough may or may not be present. Physical examination generally reveals a well-nourished patient with pale mucous membranes, a low blood pressure and rapid pulse, and often hæmic cardiac murmurs. Later frank congestive cardiac decompensation (see pp. 853–857) may ensue. The blood picture resembles that of pernicious anæmia with megalocytes and often nucleated red cells present in the blood smears. Red cell counts of between 500,000–1,000,000 erythrocytes per c.mm. are not uncommon. The colour index generally exceeds unity. The mean corpuscular volume is increased, and the Price-Jones curve shows a shift to the right, and an increased variability and mean corpuscular diameter. Leucopenia is common, the reticulocytes are not increased, the serum bilirubin values are normal and the fractional test meals show that, unlike pernicious anæmia, the oxyntic cells retain their power of secreting HCl after the administration of histamine.

In the *hæmolytic type* of tropical macrocytic anæmia, certain features are superadded. The spleen is invariably enlarged and hard but not tender. Petechial eruptions involving the skin, epistaxis and bleeding gums or bleeding from other mucous membranes occur in about 25 per cent. of cases, and are invariably associated with thrombocytopenia. An icteroid tinting of the skin or conjunctivæ is not uncommon, while hyperbilirubinæmia and dark brown stools are characteristic findings. The blood picture resembles in many respects the megalocytic anæmia already described, but reticulocytosis is the rule, and megalo-spherocytosis may be found which is not the case in the non-hæmolytic type. Leucopænia and thrombocytopænia are frequent findings. Apart from cardiac decompensation, the more common complications include uterine sepsis in the puerperium, *B. coli* infections of the genito-urinary tract, and respiratory infections; the last is predisposed to by the increased pressure on the diaphragm exerted from below by the pregnant uterus and greatly enlarged spleen, which so many of these patients present. Typical paroxysms of malarial fever at this late stage are rare, and parasites are not demonstrable between attacks.

Diagnosis.—An adequate hæmatological investigation is essential in diagnosis. The non-hæmolytic type has to be distinguished from other megalocytic anæmias. It differs from pernicious anæmia in that HCl is secreted in response to histamine injections, and nervous manifestations are absent, while the atrophic, distended abdominal parietes, marked loss of weight and the bulky pale fatty stools so characteristic of tropical sprue are not observed in tropical macrocytic anæmia. The hæmolytic type clinically resembles acholuric family jaundice, but there is no family history, the corpuscular fragility is not increased to hypotonic saline solutions, and the anæmia is of an entirely different type in the two diseases.

Prognosis.—Balfour estimated the death-rate as 40 per cent. before the introduction of liver therapy. With modern treatment and in the absence of complications patients whose condition is diagnosed at a reasonably early stage should recover completely. The non-hæmolytic type responds more readily than the hæmolytic type, in which very large doses of liver parenterally may be necessary.

Treatment.—Prophylactic.—Prevention depends on the adoption of a well-balanced diet containing adequate amounts of protein of good biological value and vitamin B_2 complex.

Curative.—Uncomplicated cases of non-hæmolytic type generally respond to marmite (Wills) in a dosage of 30 grammes daily, to liver extract by the mouth equivalent to 1 lb. of fresh liver daily, or to daily injections of 2 c.c. of injection of liver (campolon type). Maximal reticulocytosis develops about the seventh to ninth day, and provided treatment is maintained satisfactory blood regeneration follows.

In the hæmolytic variety, or where complications exist, much larger daily doses of marmite (60 grammes) or preferably of parenteral liver extract (6–8 c.c.) are necessary, and in severely ill patients, it is often advisable in addition to parenteral liver therapy to give an immediate blood transfusion (20 fl. oz.) in order to tide the patient over the critical few days before specific therapy initiates the hæmopoietic response. Successful termination of labour and the cessation of lactation decrease the nutritional demands on the body and may result in spontaneous cure, but it is important

to remember that skilled medical and nursing attention during the puerperium, and the daily examination of the patient for the onset of complications such as cardiac failure and pulmonary infections may result in saving the patient. Throughout treatment a nutritious diet containing meat, eggs, milk, and foods rich in vitamin B_2 complex is desirable.

G. Carmichael Low.
N. Hamilton Fairley.

SECTION VIII

DISEASES OF THE ENDOCRINE GLANDS

DISEASES OF THE PITUITARY GLAND

THE pituitary, a small gland, 0·5 gm. in weight, is situated in the sella turcica in close relation to the optic nerve, and connected to the base of the brain by the infundibular stalk. It is 13 mm. broad, 9 mm. from back to front, and 6 mm. high. Apart from its own special functions, it has a stimulating effect on most of the other ductless glands, which latter tend to atrophy after removal of the pituitary gland (hypophysectomy). The influence, however, is reciprocal and hyper- or hyposecretion of the other endocrine glands influences the activity of the pituitary. The hypothalamus, on either side of the third ventricle, contains many nerve nuclei which are connected with the pituitary gland. They provide the mechanism for an intimate relationship between hypothalamic stimuli and pituitary function.

The anterior lobe of the pituitary gland arises from an upgrowth of the buccal ectoderm (Rathke's pouch); and the posterior part is a downgrowth from the floor of the fourth ventricle, continuity with the latter being maintained by the infundibular stalk. In the fœtus, a cleft appears in the posterior part of the anterior lobe, separating off a few layers of cells which, lying between the anterior and posterior lobes, are termed "pars intermedia." The cleft tends to disappear in adult life. A tongue-like projection of the anterior lobe towards the tuber cinereum is called the *pars tuberalis*. The anterior lobe is composed chiefly of three kinds of cells, classified according to their staining properties: cells which absorb but little stain are termed chromophobe (60 per cent.); those taking eosin, eosinophil cells (29 per cent.); and those taking a basic dye, basophil (11 per cent.). It is probable that the chromophobe cell can give rise to both eosinophil and basophil cells. The relative proportions of the different types of cells varies with physiological conditions, such as pregnancy or the climacteric, and with experimental conditions, such as castration or adrenalectomy.

The posterior lobe secretes two hormones, pitressin and oxytocin. The former has a vaso-pressor action, is anti-diuretic, and produces an increased urinary excretion of chloride. The latter, oxytocin, produces contraction of the pregnant uterus. Recently, it has been shown that pitressin causes contraction of the non-pregnant uterus. The pars intermedia secretes the melanophore expanding hormone, which produces dilatation of the pigment spots of the frog; and probably also the specific katabolic factor of Collip, which has not yet been separated from the melanophore-expanding hormone. This Collip katabolic factor raises the metabolism, even in the absence of

the thyroid gland; and it also appears to have a ketogenic, diabetogenic and glycotrophic action, and can antagonise the hyperglycæmic effect of adrenaline.

The anterior pituitary gland appears to secrete 10 or more hormones, but it is uncertain whether they are all distinct chemical substances. It has been postulated that one hormone may have different actions under varying physiological circumstances. Description is facilitated by assuming the existence of separate hormones:

1. Growth-producing hormone.
2. Lactogenic hormone. This initiates and maintains mammary secretion.
3. Thyrotrophic hormone (thyrotrophin). This produces (*a*) hyperplasia of the thyroid gland and hypersecretion of thyroxine; and (*b*) exophthalmos, even after thyroidectomy.
4. Gonadotrophic hormone (gonadotrophin). This factor has been chemically separated into two components, Prolan A and Prolan B, which under certain conditions produce different gonadotrophic reactions. Thus, Prolan A stimulates development of the Graafian follicles and of the spermatic tubules; whereas Prolan B produces luteinisation of mature follicles, or of the theca of immature follicles, and hyperplasia of the interstitial cells of the testis or ovary. Some doubt the absolute qualitative differentiation, and, with large doses over long periods, the actions of both factors can be obtained with an extract thought to represent only one factor.
5. Diabetogenic hormone. This hormone produces hyperglycæmia, glycosuria and ketonuria. The effect appears after 2 or 3 daily injections, and owing to the appearance of anti-bodies cannot be sustained ordinarily for more than a few weeks. If, however, the daily dose of hormone is progressively increased, permanent diabetes results even when injections cease, and the islets of the pancreas are then seen to have undergone degeneration. The diabetogenic hormone can act in the absence of the adrenal glands; but their presence augments the diabetogenic effect, since they undergo cortical hyperplasia (associated adrenotrophic hormone) and this itself tends to produce hyperglycæmia. A diabetogenic effect is best seen on the hypophysectomised depancreatised dog (Houssay dog). Secretion of the diabetogenic hormone may be produced by electrical stimulation of the ventro-medial nuclei of the hypothalamus.
6. Glycotrophic hormone. A glycotrophic factor of anterior pituitary extracts can antagonise, or prevent, the hypoglycæmic action of insulin without, however, having the power to produce hyperglycæmia. It is part of, but can be separated from, the diabetogenic complex, and it is probably more correct to refer to it as a factor rather than a hormone. It is also closely associated, but not identical, with prolactin. The glycotrophic factor acts by preventing glycogen formation by insulin. It does not depend upon the presence of the adrenals or thyroid glands for its efficacy.
7. Ketogenic hormone. This produces ketonæmia, ketonuria and an increase of liver fat. It can be separated from diabetogenic anterior lobe extracts.

8. Pancreatotrophic hormone. This produces hyperplasia of the islets of Langerhans, and increased secretion of insulin. Its separate entity is not certain, and the initial action of the diabetogenic hormone in certain species appears to be pancreatotrophic.
9. Adrenotrophic hormone (adrenotrophin). This produces hyperplasia of the adrenal cortex. As with other tropic hormones, the effect is best demonstrated after the hypoplasia, or atrophy, of the adrenal cortex that follows hypophysectomy. It is associated with but can be separated from the thyrotrophic factor.
10. Parathyrotrophic hormone (parathyrotrophin). This has been described but its existence is not firmly established.

It is not always possible to classify diseases of the pituitary gland into hyperfunction and hypofunction of its various components. If one attempts to do so it would appear that gigantism, acromegaly and Cushing's basophilism syndrome are due to hyperfunction of the anterior lobe; infantalism and dwarfism (certain types) and Simmonds's cachexia to hypofunction of the anterior lobe; diabetes insipidus to hypofunction of the pars posterior and intermedia; and diabetes tenuifluus to hyperfunction of the pars posterior and intermedia. Fröhlich's syndrome is probably due to hypofunction of the anterior lobe (but adiposity is also associated with hyperfunction of the anterior lobe, as in Cushing's syndrome). An attempt to correlate the various disorders with the types of cells can only be incompletely successful, since there are 10 known functions and only 3 types of cells. Fortunately there are well-known clinical syndromes which will form a basis for the subsequent considerations.

ACROMEGALY

Definition.—Acromegaly is a condition due to a hypersecretion of the growth hormone of the anterior pituitary gland. It is characterised by enlargement of the hands and feet, and of the bones and cutaneous tissues of the face, and by splanchnomegaly. It is frequently superimposed on gigantism.

Ætiology.—The disease occurs at any age but usually before 40, and in both sexes. There is a mild familial type. The immediate cause is an excessive secretion of the growth hormone.

Pathology.—There may be an adenoma of the pituitary gland consisting of eosinophil cells, or merely a relative hyperplasia of these cells. There may be enlargement of the adrenal cortex, the thyroid and the parathyroids. The testes and ovaries are usually atrophic. The islets of the pancreas may be hyperplastic or atrophic. Diffuse lymphoid hyperplasia is frequent. All the viscera are enlarged.

Symptoms.—The patient may first seek advice because of increasing size of the hands and feet, or of a blunting and distortion of facial features, or visual disturbance due to a pituitary tumour. The latter is associated with optic atrophy, bitemporal hemianopia, progressive loss of vision and severe headaches. Ocular palsies may result from pressure on the third, fourth or sixth nerve.

The enlargement of the extremities is partly due to bony enlargement and thickening, but there is also overgrowth of the soft tissue. The vault

of the skull may be somewhat thickened, but considerable bony overgrowth is more common in the base of the skull and in the facial bones. The overgrowth of the lower jaw leads to prognathism and spreading of the teeth. The vertebræ undergo changes, and kyphosis and scoliosis are common. The soft tissues of the face, nose, and lips undergo hypertrophy, which together with the bony changes, may transform the facial appearance. The skin and subcutaneous tissue are thickened, and the sebaceous and sudoriferous glands hypertrophied, producing a greasy perspiring skin. The hair too is thick and greasy, and may be abundant over the trunk. Enlargement of the tongue leads to difficulty in articulation, and enlargement of the larynx produces a deep voice. Speech is also sluggish and memory poor. The general behaviour may be characterised by apathy and lack of initiative. Generalised muscular hypertrophy may initially be associated with great strength, but later weakness and atony result. The heart is enlarged, but hypertension or hypotension may occur.

Complications and Sequelæ.—1. Thyroid—exophthalmic goitre rarely complicates acromegaly. More commonly there is an increased basal metabolic rate without other features. The thyroid gland is diffusely enlarged in some 50 per cent. of cases, but this is not necessarily associated with thyroid symptoms or even with a raised metabolism. Sometimes myxœdema follows hyperthyroidism or may be produced initially. 2. Adrenals. Virilism in the female and increased hirsutism in the male may be prominent features, suggesting adrenal hyperplasia resulting from an adrenotrophic stimulus. 3. Diabetes Mellitus. This disorder is present in a small proportion of patients; but some degree of intermittent or chronic hyperglycæmia with glycosuria, in the absence of diabetic symptoms, may be detected in some 50 per cent. The pituitary diabetogenic hormone is probably responsible. 4. Diabetes Insipidus or Diabetes Mellitus. There may be in different patients, or in one patient in different phases of the disorder, evidence of deficiency or excess of the anti-diuretic hormone. 5. Mental Changes. Depression, irritability, negativism, melancholia, mania and delusional insanity are possible complications.

Prognosis.—The course is gradually progressive, with intermittent phases of apparent arrest of the pituitary hyperfunction. These phases may be prolonged over many years. As myxœdema may follow exophthalmic goitre, so hyperactivity of the pituitary may be succeeded by hypoactivity, with secondary hypofunction of the thyroid and adrenal glands.

Diagnosis.—The increase in size of hands and feet, and thickening and blurring of the facial features, with prognathism, makes diagnosis easy, especially if gigantism is already present. Osteitis deformans is a bony disorder which distorts the vault of the skull and does not affect the facial bones. In acromegaly, radiographic examination may reveal an enlargement of the sella turcica, which if associated with optic atrophy or bitemporal hemianopia, indicates a pituitary tumour.

Treatment.—If there is progressive involvement of the optic nerves, with danger of complete blindness, the treatment is surgical removal of the pituitary tumour. Otherwise deep radiation of the pituitary region should be tried first, and relief results in some 50 per cent. If sight is not threatened, and there appears to be an arrest of pituitary hyperfunction, treatment is symptomatic, including hormone substitution where indicated, *e.g.* thyroid

for myxœdema, testosterone for impotence, and œstrone for amenorrhœa. Exophthalmic goitre may be treated by radiation of the thyroid, or thyroidectomy. True diabetes mellitus will need dietetic regulation and insulin, but symptomless glycosuria can be ignored.

GIGANTISM

This is a condition of rapid and excessive growth of bone resulting, among other manifestations, in a height above normal. Like acromegaly, it is due to excessive secretion of the growth hormone by the eosinophil cells of the anterior pituitary (hyperplasia or tumour), but this hypersecretion operates in childhood, or adolescence, before the epiphyses of the long bones have united. If the hypersecretion persists, acromegaly will be superimposed on the gigantism. In uncomplicated gigantism, there is no sharp dividing line between normal tall people and pathological giants, and the characteristic of tallness is probably a familial and racial feature dependent upon constitutional hyperactivity of the anterior pituitary. Eunuchoid individuals, as well as pre-pubertal castrates, are often excessively tall. This may be due to two factors: (1) growth hormone acting over a longer period, since the union of the epiphyses is delayed; and (2) hyperactivity of the anterior pituitary secondary to failure of gonadal function, assuming the latter to be primary.

The treatment of pathological gigantism is the same as for acromegaly, namely, radiation of the pituitary gland, or surgical removal of a pituitary neoplasm. Inhibition of pituitary activity by large doses of testosterone, or œstrone, may be of some benefit.

CUSHING'S BASOPHILISM SYNDROME

Synonyms.—"Multiglandular syndrome of the fat-bearded diabetic woman"; Achard-Thiers syndrome.

Definition.—A condition of virilism in females (or of feminisation in males) associated with adiposity, hypertension, diabetes mellitus, plethora, and softening of the bones.

Ætiology.—The disease is commonest in the second and third decades, but may occur at any age. It is much more common in females than males. The immediate cause is a hypersecretion of the anterior pituitary (especially of the basophil cells), and an associated hyperplasia of the adrenal cortex.

Pathology.—Cushing found the essential feature to be an adenoma of the basophil cells of the anterior pituitary. It is now established that the complete chemical picture may result from a neoplasm or hyperplasia of the adrenal cortex, or more rarely from a neoplasm of the thymus gland, or even from a chromophobe adenoma of the anterior pituitary. Although a basophil adenoma is not always present, hyalinisation of the basophil cells of the anterior pituitary is a common feature. Crooke believes that it is responsible for all features of the syndrome except virilism or feminisation. The latter two features are very probably resultants of the hyperactivity of the adrenal cortex, which in some cases is primary and in others secondary.

Symptoms.—Virilism is shown by cessation of menstruation, loss of hair of the head, and growth of hair on the face and body, as in the male; feminisation is indicated by testicular atrophy and impotence, and by mammary development. For a fuller description the reader is referred to the subsection on Diseases of the Suprarenal Glands. In all cases the adiposity is diffuse, but it is especially noticeable on the face, trunk, and upper arms and thighs. It is occasionally a painful adiposity. Where the skin has been stretched by fatty deposits, *e.g.* in lower abdomen, thighs, breasts, and axillæ, there are linea distensæ, which are not white but of a deep red colour. The face is plethoric and of a dusky tinge, suggesting a polycythæmia basis, which is not necessarily substantiated by a red cell count. The anterior aspects of the legs show bluish mottling with contrasting patches resulting in a marble appearance, from which is derived the dermatological name, cutis marmorata.

The bones are rarefied (seen in X-ray photographs) and softened, so that the vertebrae are compressed, and the patient develops kyphosis and round shoulders, with a diminution in height. Lordosis helps to accentuate an adipose pendulous abdomen, and may give rise to troublesome backache. The blood pressure is raised, and there may be a secondary ischæmic nephritis. In a few patients, fatal malignant nephrosclerosis has been recorded. Diabetes mellitus may be present in varying degrees of severity, and those patients who manifest no diabetic symptoms invariably show a delayed fall in blood sugar in the carbohydrate tolerance test. Pigmentation of the orbits and nipples may be present. Migrainous headaches are not infrequent, but changes in the optic nerves or visual fields are rare, since basophil adenomas are usually microscopic in size. The thyroid gland may be enlarged, but there is rarely evidence of hyperthyroidism.

Complications.—The patients are liable to intercurrent infections, especially staphylococcic.

Diagnosis.—Adipose corpulent women with plethoric faces, rounded shoulders, and hirsutism, suggest the diagnosis. Radiograms may show osteoporosis, but the sella turcica is usually not enlarged. Glycosuria and hypertension are additional features. Hirsutism is of male distribution, but quite frequently not excessive. The possibility of an adrenal tumour is suggested by considerable hairiness, gross enlargement of the clitoris, and a gross excess of androgenic hormone in the urine (*e.g.* more than 300 capon units daily). In doubtful cases, iodoxyl (pyelectan, uropac, uroselectan) radiographic examination, or perirenal insufflation, or even laparotomy is called for (see adrenal section). Thymus tumours can be excluded by radiographic examination of the chest, and ovarian tumours (a rare cause) by bi-manual examination. The urinary calcium excretion may be increased, but the serum calcium is not raised, as in the case of hyperparathyroidism.

Mild and incomplete forms of Cushing's syndrome are not at all uncommon, and are often familial. They do not necessarily call for any special treatment. It is questionable whether they are more correctly regarded as variants of normality than as pathological.

Prognosis.—In the absence of treatment, the course is usually progressively downhill, but only gradually so. As with acromegaly, there may be spontaneous arrest of the process for many years. If an adrenal tumour is removed surgically, in the absence of malignant recurrence the patient may

return to complete normality. In the case of basophil adenoma, deep radiation applied to the pituitary gland may be followed by remarkably good results, with disappearance or considerable amelioration of most symptoms, including the diabetes mellitus.

Treatment.—An adrenal tumour should be removed surgically. A thymus neoplasm is malignant and deep radiation of the thymus area is unlikely to prove of more than temporary benefit in such cases. In the absence of proof of any primary lesion outside the pituitary gland, a basophil adenoma is assumed, and deep radiation applied to the pituitary gland. Unilateral adrenalectomy for a supposed bilateral hyperplasia of the adrenal cortex is illogical, and cannot produce appreciable amelioration.

DWARFISM

Synonym.—Infantilism; Levi-Loraine Syndrome; Brissaud's Infantilism.

Definition.—By dwarfism is meant a failure to grow, resulting in subnormal height, and due to a deficient secretion of growth hormone by the anterior pituitary gland. It may or may not be accompanied by other endocrine stigmata. Infantilism is a variety of dwarfism, implying a degree of growth and also of sexual development not qualitatively abnormal but not commensurate with the age of the individual. The term was first used by Loraine in 1871 in connection with a case of infantilism associated with tuberculosis. It was later applied by Levi (1908) to hypopituitarism beginning in childhood. Brissaud extended the term to include infantilism associated with hypothyroidism (Brissaud's infantilism).

Ætiology and Pathology.—In both dwarfism and infantilism there may be a pituitary tumour, usually chromophobe adenoma, or a parapituitary tumour. In most cases, however, there is no gross lesion. One can postulate a hypoplasia of the eosinophil cells, since these secrete growth hormone. In colonies of congenitally dwarfed mice there is a relative diminution in the proportion of eosinophil cells. Dwarfism may be part of the Fröhlich syndrome, or of cretinism. In pathological sexual precocity, and in some otherwise normal people, dwarfism appears to be due to premature closure of the epiphyses. Inadequately treated diabetic children fail to grow at the normal rate.

Non-endocrine causes are rickets, renal rickets, fragilitas ossium, coeliac disease, pancreatic disease, von Gierke's glycogen disorder, vitamin deficiency, and achondroplasia. There is no evidence of an endocrine basis for achondroplasia.

Symptoms.—In the majority of cases, the only features are a failure to grow at the normal rate and (or) a cessation of growth at an early age. Normally the epiphysis of the lower end of the femur closes at 18 or 19, but that of the head may close as early as 15 or as late as 18. The majority of normal boys continue to grow after puberty, but some 30 per cent. of girls cease to grow after menstruation has commenced. In the latter cases, there may be premature union of the epiphyses. Failure to grow adequately is not usually associated with that of sexual development, but the latter is an essential feature of Levi-Loraine infantilism. Failure to attain an average height is

often familial, and one family may have both very tall and very short members, their numbers determined by Mendelian laws. The mechanism, however, as with congenitally dwarfed mice, is through the anterior pituitary gland.

Diagnosis.—With simple failure of growth, or in infantilism, the relative proportion of arms, legs and trunk is normal. In achondroplasia, the arms and legs are short compared with the body (human dachshund), and the nose is broad and flat. It is important to radiograph the epiphyseal junctions, since growth hormone cannot act after epiphyseal union.

Prognosis.—Growth hormone is not effective in all cases of subnormal growth. It is obviously useless if the epiphyses have prematurely united. It may be equally so in endocrine dwarfism if not applied until adult life, even when the epiphyses remain ununited. This is in keeping with the observation that growth hormone fails to be effective in the hypophysectomised animal if its use is too long delayed. Growth hormone is sometimes ineffective in cases where one might expect good results and there is probably an important genetic factor to be considered. Nevertheless therapy with growth hormone is worth trying and good results are obtained.

Treatment.—The essential treatment of deficient growth is anterior pituitary growth hormone, 100 to 200 rat units weekly, in two or three divided doses, administered intramuscularly in the buttock. There may be painful local reactions which, however, tend to diminish with repeated injections. As an anti-growth principle develops in the blood, injections should not be continued for more than 6 weeks, but may be repeated after an interval of 2 months. Thyroid extract, $\frac{1}{2}$ gr. to 1 gr. daily, is valuable, especially if there is some evidence of thyroid deficiency, but even in other cases. There is no reason to believe that anterior pituitary tablets by mouth are efficacious. In infantilism, the question of hastening sexual maturity by gonadotrophic hormone arises, but some feel that this effect might produce union of the epiphyses and prevent growth. On the other hand, most boys continue to grow after the sexual maturity of puberty.

SIMMONDS'S DISEASE

Synonyms.—Pituitary Cachexia; Hypopituitarism.

Definition.—A disorder due to destruction or atrophy of the anterior pituitary gland, and manifested by cachexia, anorexia, subnormal metabolism, and hypogonadism.

Ætiology.—The disease is more common in women since the commonest cause is atrophy of the anterior pituitary resulting from a local vascular lesion during the puerperium. Multiparæ are especially prone. It may, however, occur at any age and in either sex associated with a pituitary or parapituitary tumour.

Pathology.—Simmonds's original case showed atrophy and fibrosis of the anterior pituitary gland as a result of an embolus in the main artery in a fatal case of puerperal fever. The vascular lesion is, however, more commonly thrombosis. Suprasellar cystic tumours and chromophobe adenomata are other important causes, and rarely malignant metastases, tuberculosis, syphilis, and xanthomatosis. An unusual but important ætiological occurrence is simply diminution in the relative number of eosinophil cells. As in the

case of hypophysectomy, the gonads, thyroid and adrenal cortex are hypoplastic or atrophic. The viscera are diminished in size in contrast to the splanchnomegaly of acromegaly.

Symptoms.—Weakness, wasting, and anorexia are cardinal features, but of equal importance is the invariable failure of sex function. Thus, in the female, amenorrhœa is associated with a hypoplastic or infantile uterus, and, in the male, the gonads and penis fail to develop or, if already adult in size, they undergo atrophy. In both sexes the secondary sexual characteristics, *e.g.* pubic, facial and axillary hair, are lost, and the eyebrows and hair of the scalp also become thin and lustreless, or disappear. The skin is pale and dry, and may become wrinkled, giving a senile facies, known as progeria. The lower jaw may become atrophic (opposite of prognathism), and the teeth decay and fall out. The low metabolism, *e.g.* —40 per cent., is manifested by a subnormal temperature and hypersensitivity to cold. Bradycardia and hypotension are usual features. The blood sugar is also subnormal and the carbohydrate tolerance usually increased. Spontaneous hypoglycæmic attacks occur, and may be fatal. Anæmia and a relative lymphocytosis, with perhaps some degree of eosinophilia, are not uncommon.

If the disorder commences in childhood; the lack of growth hormone results in failure to grow, although the epiphyses remain ununited in adult life. The latter is probably associated with failure of sexual development.

Complications.—Pulmonary tuberculosis may follow prolonged inanition. Apathy and inertia are characteristic but may progress to melancholia, with disorientation of time and place. Optic atrophy results from tumours.

Diagnosis.—The well-developed syndrome cannot escape recognition if the disorder is kept in mind. Minor and incomplete manifestations are more easily missed, but not if the possibility of the disorder following a puerperium in which there is severe hæmorrhage and (or) infection is remembered. Migrainous headaches can occur even in the absence of a pituitary or parapituitary tumour, but radiographic examination of the sella turcica and examination of the fundi for optic atrophy should not be omitted.

There are many features in common with Addison's disease, but pigmentation in Simmonds's cachexia is either absent, or very slight, and is never present in the mucous membranes. Anorexia nervosa in the late stages may show all the features of Simmonds's cachexia, and it is probable that there is an inhibition of pituitary activity via the hypothalamus. The initial and fundamental cause of anorexia nervosa is, however, psychogenic. It usually occurs in young adults, more often in females, and it is possible to elicit a history of psychic trauma, shock, disappointment, or emotional upset. In contrast to the apathy of Simmonds's cachexia, these patients are restless and perform feats of activity far beyond their apparent strength ; the loss of sexual hair is rarely extreme and may not occur ; in contrast, the trunk and perhaps the face is covered by diffuse downy hair.

Prognosis.—There is usually progressive deterioration, but patients with minor manifestations following pregnancy may recover spontaneously. Treatment is only moderately beneficial.

Treatment.—The only rational treatment is substitution therapy, and this can only be of a limited nature. Cortin, or desoxycorticosterone, will help as replacement therapy for adrenal cortical function. It produces an

increase in strength and weight. Gonadotrophic hormone and œstrone, or testosterone, may establish or to some extent replace sex function, but has no influence on the general asthenia. Thyroid is rarely beneficial and may be harmful even although the metabolism is low. Glucose counteracts hypoglycæmia. Treatment in well-developed cases is rarely entirely satisfactory, and optimistic reports of complete success raise the query of accurate diagnosis.

In the milder forms following pregnancy, the question of the advisability of another pregnancy must be considered, should the latter prove a possibility. It is established that some patients may thus make a complete recovery since the uninjured part of the anterior pituitary undergoes hyperplasia during pregnancy. If, however, the subsequent parturition is complicated by severe hæmorrhage or infection, further thrombosis may occur in the pituitary and the patient may die.

FRÖHLICH'S SYNDROME

Synonym.—Dystrophia Adiposo-Genitalis.

Definition.—A combination of adiposity and hypogonadism, usually occurring at or before puberty, and resulting from pituitary hypofunction, or dysfunction.

Ætiology.—The condition occurs in both sexes, and may be familial. Fröhlich's original case was a boy of 14 with a craniopharyngioma.

Pathology.—A small proportion of cases are due to a parapituitary tumour (cranio-pharyngioma), or more rarely to a chromophobe adenoma of the anterior pituitary. The majority, however, are not associated with a gross pathological lesion, and autopsies are rare. The lesion is sometimes in the hypothalamus rather than in the pituitary, *e.g.* encephalitis, meningitis, syphilis, and hydrocephalus.

Symptoms.—Adiposity and hypogonadism are the two essential features, but to these may be added in some cases a failure of growth hormone and dwarfism. The fat is deposited in girdle and symmetrical fashion, on the abdomen, shoulders, thighs, upper arms, mammary region, mons veneris, face and neck. The adiposity may be present from early childhood, although the syndrome is at its maximum at puberty. The legs and forearms are thin and graceful, and the fingers are usually narrow, delicate and tapering, but occasionally short. The deposition of fat is of feminine type, so that the bodily configuration of the affected male resembles that of the female. There is often a pad of fat over the lower cervical vertebræ. The skin over the outer aspect of the upper arms, thighs and buttocks shows a blueish-red mottling.

Hypogonadism in the male is shown by minute testicles, one or both of which may be undescended, and by a subnormal penis. There is little or no hair over the axillæ and pubis; and, if present in the latter site, it is of feminine distribution, being limited horizontally and not extending upwards to the umbilicus. The skin of the face is smooth, delicate and hair-free, and the complexion good. The voice is high-pitched and does not break. The walk is feminine, and the buttocks tend to sway from side to side as in the female. The feminine habit of resting the hand on the waist or knee is not uncommon. In the female the uterus is infantile, and amenorrhœa, or scanty

menstruation at long intervals, is usual. The breasts are large, but this is caused by fat, and not by glandular tissue. A tendency to sleepiness, like the fat boy in *The Pickwick Papers*, and a craving for sweet things are other features. The basal metabolic rate is normal. The mental and emotional colouring of the personality is characteristic. Periods of depression and introspection alternate with joyousness, high spirits, and euphoria. The patients are excellent company, and very popular with their school friends. They are usually musical and imaginative, with intellectual ability often above normal.

Complications.—Rarely the syndrome is complicated by the additional features of retinitis pigmentosa, mental deficiency, polydactylism and familial incidence. It is then called the Laurence-Moon-Biedl syndrome, and the patient is usually of the Hebrew race.

Diagnosis.—Unless definite hypogonadism is present, the diagnosis of Fröhlich's syndrome is not justified, but is nevertheless frequently made. This is because of lack of supplementary nomenclature. Puberty adiposity may occur with normal genital development, or even with some degree of sexual precocity, or with some features of Cushing's syndrome. In all cases it is probably endocrinological. A parapituitary tumour is indicated by optic atrophy and enlargement or distortion of the sella turcica, as seen in radiograms.

Prognosis.—The disease may be transitory, the adiposity decreasing with belated sexual development. More often it is chronic, with phases of accentuation and amelioration.

Treatment.—Gonadotrophic hormone, 500 units twice weekly for 6 weeks or more, will tend to produce sexual maturation but rarely influences the adiposity. The latter may be modified by restricted diet and thyroid. It is irrational to employ the latter in doses greater than 1 gr. of the dried gland daily, since the basal metabolism is not subnormal. The adiposity is unlikely to be fundamentally altered by any therapy at present employed. Parapituitary tumours may call for surgical removal if sight is threatened. Deep radiation of the pituitary region may be of benefit.

ADIPOSITY

Definition. Adiposity is an excessive deposition of fat in the subcutaneous tissue.

Ætiology and Pathology.—There are four main groups: (1) Exogenous—eating of excessive food. (2) Associated with endocrine syndromes: (*a*) Fröhlich's; (*b*) Cushing's; (*c*) Adrenogenital; (*d*) Dercum's disease—adiposis dolorosa; (*e*) following castration or the menopause; and (*f*) Hyperinsulinism (pancreatic tumour or hyperplasia). (3) Hypothalamic lesions, *e.g.* encephalitis, tabes, hydrocephalus. (4) Idiopathic constitutional.

The eating of an excessive amount of food may be due to habit, greed, or anxiety, but there is also a centre in the hypothalamus, a lesion of which appears to produce pathological hunger, as is seen in certain brain tumours. This may also operate in apparent idiopathic adiposity. The mere eating of an abundance of food is probably not the only factor, for anxiety states producing excessive appetite may nevertheless be associated with leanness

and an inability to put on flesh and fat. On the other hand, the majority of cases of idiopathic adiposity cannot be ascribed to food intake and it cannot be doubted that of two people on similar diet, or of two children of the same family on similar diet, one of each can be fat and the other thin. I am of opinion that it is probable that in both exogenous and idiopathic constitutional adiposity there is an underlying disturbance of the hypothalamic pituitary mechanism.

Symptoms.—Whatever the ætiology, the fat is usually deposited on the face and neck, breasts, abdomen, suprapubic area, buttocks, upper arms and thighs. Linea distensæ, which are white, except in Cushing's syndrome, when they are dusky red, appear in the overlying skin which has been stretched. Many of the idiopathic types of adiposity display in minor degree features of endocrine syndromes, *e.g.* hirsutism, scanty or infrequent menstruation, and impaired carbohydrate tolerance. Diabetes mellitus of middle age is more frequent among the adipose, and adiposity is therefore said to predispose to diabetes. It is more probable that both are due to a common pituitary lesion. It is interesting to note that when amenorrhœa is associated with adiposity, dietetic measures alone, if successful in reducing weight appreciably, may sometimes produce a return to normal menstruation. Fat is also deposited in the viscera, especially the liver and heart, and sudden heart failure does occur in extreme cases. In adiposis dolorosa, symmetrical deposition of painful fatty deposits is associated with an unstable weeping temperament.

Complications.—Diabetes mellitus, cholelithiasis, heart failure, arthritis, varicose veins, and flat feet are some complications.

Diagnosis.—In the majority of cases it is impossible in the present state of knowledge to define the underlying lesion, and therefore the vague terms idiopathic or pituitary adiposity are used, not without some justification. The recognition of the more obvious endocrinopathies presents no difficulty but minor manifestations may escape recognition.

Prognosis.—The condition tends to be chronic, with periods of amelioration and relapses.

Treatment.—This is most unsatisfactory. We have no direct attack on the essential dysfunction, neither do we know as yet whether it is essential hypofunction or hyperfunction. If the latter be true, as suggested by Cushing's syndrome and by adrenal cortical syndromes, it is useless to seek substitution therapy. Thyroid to the point of tolerance as judged by pulse rate is of limited value, as one might expect on account of the basal metabolism in adiposity being already normal or above normal. More toxic accelerators of metabolism, such as dinitrophenol, have now been abandoned. Collip's pituitary katabolic factor may prove useful, since the resulting lowering of the respiratory quotient suggests a specific attack on fat metabolism.

Low caloric diets, *e.g.* 1000 calories daily, will produce a reduction in weight, if strictly adhered to. It is rare, however, for the patient to enjoy good health and well-being on such a diet over a long period, and any minor departures from a food intake well below normal will produce increase in weight. The basis of such diets is the avoidance of fatty, sweet and starchy foods, and their substitution by green vegetables, salads and non-fatty meat. Alcohol, especially beer, should be avoided, as it tends specifically to adiposity in some patients apart from its caloric value. Salt-free diets and injections

of mercurial diuretics for a hypothetical salt water-retention type of adiposity have been advocated, but it is rare to find such an uncomplicated type of adiposity and the effects can only be temporary. Massage and exercise are helpful but not fundamental measures.

Since with the present available therapeutics it is difficult, if not impossible, to change fundamentally a constitutional fatty type, it is important to attempt to counteract any associated hypersensitivity by a psychotherapeutic approach and a philosophical evaluation.

DIABETES INSIPIDUS

Definition.—Diabetes insipidus is a disturbance of water balance, characterised by polyuria and polydipsia, but due to a destructive lesion of the posterior or intermediate lobe of the pituitary gland, or of the adjacent part of the diencephalon.

Ætiology.—The condition is sometimes familial. It may occur at any age and in either sex. It is due to a deficient secretion of the anti-diuretic hormone by the posterior lobe of the pituitary. This results from destruction of the lobe, or any interruption of its normal connection with the supra-optic nucleus of the hypothalamus. Such a lesion is followed by degeneration of the pars nervosa, but not of the pars intermedia. The anterior pituitary lobe must be present for diabetes insipidus to result, and it probably has a diuretic action by an indirect effect on metabolism. It is doubtful if the anti-diuretic hormone of the pars nervosa has been separated from the vaso-pressor hormone. In addition to decreasing the amount of urine excreted, this hormone also increases the amount of chloride excreted in the urine.

Pathology.—The lesion in the hypothalamic-pituitary mechanism may be traumatic, vascular, syphilitic or tuberculous meningitis, primary or metastatic brain tumour, acromegaly, or Hand-Schüller-Christian's disease. The condition may also follow shock, via the hypothalamic mechanism. In the majority of cases, there is no obvious cause (idiopathic).

Symptoms.—The symptoms are polyuria and polydipsia, with the passage of large quantities of urine, *e.g.* 12 litres in 24 hours, of pale colour, and low specific gravity, *e.g.* 1002. The polyuria leads to disturbed sleep and anxiety. The patient loses weight and strength, and may become very emaciated and even bedridden if untreated.

Diagnosis.—Hysterical polyuria may be difficult to differentiate apart from the hysterical background. There is a tendency in this condition, however, for the polyuria to be more marked during the daytime and the patient may sleep throughout the whole night, whereas the polyuria of diabetes insipidus is most troublesome at night. The hysterical patient remains in reasonably good health in spite of the polydipsia and polyuria. Some individuals have a familial hypersensitivity to caffeine diuretics and, if much tea or coffee is drunk, they have polyuria and frequency. Diabetes mellitus is easily distinguished by hyperglycæmia and glycosuria. In chronic nephritis the urine may be voluminous and of constantly low specific gravity, but it contains some albumin and renal casts. A Wassermann reaction to exclude tertiary syphilis is always advisable. A radiogram of the skull, and examination of the optic disks and visual fields should exclude pituitary

and parapituitary tumours. The Hand-Schüller-Christian disease is congenital and familial and characterised by exophthalmos, large liver and spleen, yellow-tinted skin, and irregular patches of xanthomatous infiltration of the skull (radiogram).

Prognosis.—The disease is protracted, and if treatment is inadequate the patient becomes emaciated and dies from intercurrent infection.

Treatment.—It is illogical to attempt to restrict the intake of fluid severely, for experimental evidence shows that the primary disorder is the polyuria, and the polydipsia is a secondary attempt to compensate for the loss of fluid. Pitressin should be injected, 10 to 20 units subcutaneously three or more times in 24 hours. Some patients react allergically at the site of injection. Other commercial brands may then be tried, but if local reactions persist, the treatment will not be effective even if continued, as the hormone tends to be destroyed at the site of injection. Nasal insufflation of the dried powder is effective, and is carried out from a curved glass tube with two open ends or with a rubber pressure bulb attached. The patient learns to know the optimum amount of powder and frequency of application. Nasal jelly and application of the fluid on cotton wool in the nostrils are other methods. As with insulin, the dose of pitressin must be increased during periods of infection, *e.g.* influenza.

DIABETES TENUIFLUUS

Definition.—A condition of supernormal secretion of the posterior pituitary antidiuretic hormone, manifested by diminution in the volume of urine excreted and an absence of thirst. Tenuifluus means "flowing slenderly," and the condition is the opposite of diabetes insipidus (tasteless urine). The latter condition might be better termed diabetes multifluus (copious urine—flowing greatly).

Ætiology and Clinical Features.—The malady is due to excessive secretion of the anti-diuretic hormone of the pars nervosa of the pituitary. It is probable that the condition occurs rarely as an uncomplicated entity, as does diabetes insipidus, although in the comparatively few occasions that it has been observed, it has appeared to be part of a pituitary syndrome. It may be found with pituitary or parapituitary tumours, with Fröhlich's syndrome, and with other varieties of pituitary adiposity. Acromegaly may be associated either with diabetes insipidus, or with diabetes tenuifluus, and one may give place to the other according to the phase of the disease. In one such case of the latter, Ellinger, Hare and Simpson observed, for the first time, that there was an excess of anti-diuretic hormone in the cerebrospinal fluid. The daily intake of fluid was small, and the output of urine even smaller, the difference apparently being explained by an obviously excessive perspiration, in contrast with the dry skin of diabetes insipidus. It is interesting to note that radiation of the pituitary gland resulted in a normal and balanced fluid intake and output, and a disappearance of excessive perspiration and of the excess of antidiuretic hormone from the cerebrospinal fluid.

The mechanism of perspiration may not always compensate for a discrepancy between intake and output of fluid, and fluid may be retained,

with a resulting increase in weight, at any rate for a time. This may explain the premenstrual gain of weight, which may occur with normal women, but which is much greater in women with pituitary obesity. The subsequent post-menstrual loss of weight is associated with a diuresis. A disorder of water balance is also one factor in certain types of pituitary obesity, as is suggested by the response to mercurial diuretics, or sometimes to the mere adoption of the prone position.

Complications.—E. I. Jones recently described a syndrome, in a man of 26, which he attributes to hyperactivity of the posterior lobe of the pituitary gland. The main features were hypertension, hyperchromic anæmic, achlorhydria, and impaired carbohydrate tolerance. Melanophore-expanding vasopressor, and antidiuretic substances were present in the urine (Noble and others).

Diagnosis.—An abnormally small daily excretion of urine in the absence of cardiac or renal disease suggests diabetes tenuifluus, especially if accompanied by excessive perspiration for which no ordinary cause is obvious.

Treatment.—Radiation of the pituitary gland appears beneficial.

ANTIHORMONES

Collip's observation that parathormone gradually lost its effect on repeated injection first drew attention to the possibility of anti-hormones or anti-hormonic substances being produced in the human body by the injection of hormones. Since then anti-hormones have been discovered for most of the pituitary " trophic " hormones, their action being especially well studied in the case of the thyrotrophic, gonadotrophic and diabetogenic hormones. Thus, if thyrotrophic hormone (thyrotrophin) is injected into guinea pigs, the thyroid gland undergoes hyperplasia, thyroxine is secreted in excess, and the basal metabolic rate increases by, say, 50 per cent., attaining a maximum in 7 to 10 days. After this, even when injections are continued, the basal metabolic rate falls to normal or even subnormal, and the thyroid again fills with colloid, as in the resting phase. This development of refractoriness to the thyrotrophic stimulus is due to the production of anti-thyrotrophic hormone which neutralises the activity of the thyrotrophic hormone. This can be proved by injecting the serum of a guinea pig in a refractory phase into a normal guinea pig, and thus rendering the second animal immediately refractory to thyrotrophic hormone. All this is equally true of man and is an obvious stumbling block to therapy, even though experimentally the resistance can be overcome by progressively increasing the dosage of " trophic " hormone.

The term anti-hormone does not necessarily indicate that the substance is a hormone and not merely a chemical anti-body or precipitin. Collip regards a hormone—anti-hormone linkage as a normal condition, but there is no evidence that these " anti " substances are produced in the endocrine glands. It has been shown in man, as in the experimental animal, that gonadotrophic hormone of the same species (pregnancy urine) does not produce anti-hormone, whereas gonadotrophic hormone from another species (*e.g.* sheep's pituitary) does. This suggests that the mechanism is a precipitin one, but this is not always so and anti-bodies can be formed from protein-free extracts.

The practical point is to remember that if the hormone is derived from a species other than man, therapy may be ineffective after some weeks, and this especially refers to parathormone, growth hormone, thyrotrophic hormone, and some gonadotrophic hormones. Antihormones tend to disappear after several weeks, when therapy may be resumed intermittently.

S. L. SIMPSON.

DISEASES OF THE THYROID GLAND

In the absence of convincing evidence as to the existence of dysthyroidism, a division of thyroid disorders into hypersecretion and hyposecretion is at present acceptable. In the case of both, the age incidence may influence the clinical features. The essential hormone of the thyroid gland is usually considered to be thyroxine, the p-hydroxyphenyl ether of tyrosine. The colloid of the gland is thyroglobulin, a protein to which iodine is attached. On hydrolysis this yields the α-amino acids thyroxine and diiodotyrosine. Harington believes that the true active secretion contains thyroxine and diiodotyrosine linked to form a peptide. The activity of thyroglobulin is proportional to its total iodine content and not to the thyroxine contained therein. The relative insolubility of thyroxine, and the latent period after its intravenous injection, also make it difficult to accept thyroxine as the essential hormone; but even so, for the sake of convenience, this term will be used in the text.

Unfortunately a clinical classification of thyroid diseases has not a clearly defined morbid anatomical basis. This is not unrelated to the fact that hyperplasia of the gland, in the absence of sufficient iodine, may be present with the clinical manifestations of hyposecretion rather than hypersecretion. According to Marine, the thyroid gland is a very labile tissue, with a single definite morphological cycle influenced by the balance between the need for iodine and its availability. An absolute or relative deficiency of iodine leads to hypertrophy and hyperplasia of the thyroid epithelium and loss of colloid. A subsequent adequate supply of iodine produces involution to a resting epithelium and much colloid. This cycle can repeat itself, but a prolonged iodine deficiency may lead to irreversible atrophy of the gland. Experimental evidence indicates that iodine can prevent any thyrotrophic or goitrogenic agency from being effective.

A simple clinical classification is as follows:

- Hyperthyroidism
  - Graves's Disease.
  - Secondary Thyrotoxicosis.
- Hypothyroidism
  - Myxœdema.
  - Cretinism.

GRAVES'S DISEASE

Synonyms.—Hyperthyroidism; Exophthalmic Goitre; Parry's Disease; Basedow's Disease.

Definition.—Hyperactivity and hypersecretion of the thyroid gland, usually manifested by tachycardia, tremor, loss of weight, nervousness, exophthalmos, enlargement of the thyroid, and raised basal metabolic rate.

Ætiology.—The disease is more common in females than males, in the ratio of 6 to 1. This is probably associated with the greater lability of the endocrine system in the former, as indicated by the not infrequent physiological transient enlargement of the thyroid at puberty, at menstruation, and the menopause. The malady is commonest in the second and third decades, but it may occur in childhood or old age. Puberty or the menopause may be periods of initiation.

Mental stress, anxiety, shock and sexual neurosis are often precursors of the disease, but a constitutional vulnerability of the thyroid to such stimuli is probable. The latter is also indicated by a familial predisposition. Infection aggravates pre-existing hyperthyroidism, and sometimes appears to initiate the disease.

Pathology.—The cuboidal epithelial cells undergo hypertrophy and become columnar. They also divide and multiply (hyperplasia), and may project in folds into the follicles, giving a lace-like pattern. The follicles are almost emptied of colloid unless iodine has been given. Adenomata may be present. There is a generalised lymphatic hyperplasia and lymphoid infiltration of the thyroid itself. The thymus is usually enlarged. The liver may show areas of necrosis or atrophy, and is often depleted of glycogen. Experimentally, pituitary thyrotrophin will produce similar pathological changes and a raised B.M.R. in guinea-pigs and man. Nevertheless, it has not been possible to demonstrate such a hormone in the blood of patients with hyperthyroidism.

Symptoms.—The excessive secretion of thyroxine has wide systemic effects, and also disturbs the nervous stability of the patient. Many of the symptoms appear to result from overactivity of the sympathetic nervous system.

Cardio-vascular system.—Tachycardia in some degree is invariable, and is usually associated with palpitation. Extra-systoles may be present, and if the disease is of long standing or in people over 40, auricular fibrillation is not infrequent. Capillary pulsation may be seen, and vaso-motor instability is evidenced by a tendency to blush or the appearance of a characteristic patch of redness over the neck and upper sternum. The carotid and brachial vessels pulsate visibly and forcibly. The systolic pressure is slightly raised and the diastolic is normal or diminished, resulting in an increased pulse pressure. It has been suggested that hyperthyroidism may be a cause of hypertension, but the evidence is not convincing, and thyroidectomy has not been shown to produce any effect on the hypertension itself, although associated tachycardia or angina may be favourably influenced.

Nervous system.—There is a characteristic tremor of the hands, noticeable on being asked to hold out the hands, or in writing, or in lifting a cup. An anxiety neurosis is a frequent and almost invariable accompaniment of hyper-

thyroidism. The patient is also restless and unstable, and finds it difficult to remain in one position for any length of time. Conversation too is desultory and, although there is often a hyperacuity of perception and conception, this is offset by an inability for sustained effort or concentration. Increased sensitivity and sensibility trouble the patient and her associates or family, and emotional distress is common. Occasionally psychotic manifestations develop, especially paranoia and acute mania, with suicidal tendencies, but rarely does this happen in the absence of a constitutional predisposition. Sweating is often excessive, manifested by the hot, moist handshake, and it may be soaking undergarments or bedclothes. Considerable muscular wasting and weakness may be features, simulating acute bulbar palsy, or progressive muscular atrophy, or very rarely familial periodic paralysis, but they are thyrotoxic myopathies and not neurogenic in origin.

Gastro-intestinal.—The paradox of an insatiable and voracious appetite with progressive loss of weight is a source of wonder and concern to patient and relatives. The explanation is a raised metabolic rate. Excessive thirst is an effort to compensate for loss of fluid by profuse perspiration. Attacks of dyspepsia occur, sometimes with vomiting, and this may be due to hepatic disturbance, but achlorhydria and hypochlorhydria are not infrequent. Achlorhydria, or vegetative nervous irritability, may explain attacks of diarrhœa, which if severe or inadequately controlled may result in dehydration.

Ocular signs.—Exophthalmos is said to be present in 70 per cent. of cases, but if minor degrees are included the incidence is much higher. The condition is usually obvious, but early stages may be indicated by a glint in the eye, or a restless coquettish look. Although characteristically bilateral, one eye may be affected before the other, or in lesser degree, presumably because of anatomical differences. The exophthalmos is not usually associated with dilatation of the pupil. It is interesting to note that pituitary thyrotropin will cause exophthalmos, experimentally, even after paralysis of the cervical sympathetic, or after thyroidectomy. The latter fact explains why exophthalmos sometimes persists after an adequate thyroidectomy. The classical signs of exophthalmos associated with historical names have no practical significance, and are only included for examination purposes. Thus: Dalrymple's sign is the wide palpebral fissure; von Graefe's sign is lagging of the upper eyelid on looking down; Stellwag's sign is absence of blinking; and Joffroy's sign is absence of wrinkling of the forehead on looking up.

Brain has described a condition of exophthalmic ophthalmoplegia in people usually over 40, in which there is mechanical paralysis of ocular movement in one plane. One eye is nearly always more affected than the other, and diplopia is frequent. Although this severe condition may be associated with mild thyrotoxicosis, or appear after thyroidectomy, he regards it as a separate entity. Nevertheless, in both conditions, there appears to be a thyrotrophic stimulus, contractions of the orbital smooth muscle, venous compression, œdema, and ultimately swelling and degeneration of ocular muscles.

Thyroid gland.—This is almost invariably enlarged, although the degree is by no means proportional to that of the thyrotoxicosis. The enlargement usually affects both lobes, and not infrequently the isthmus. The swellings are smooth and roughly symmetrical, but one lobe may be larger than another. Small degrees of enlargement may be missed unless the proper technique

of palpation is observed. The thumb should compress the site of one lobe of the thyroid against the trachea, and the opposite lobe then becomes palpable to the thumb or fingers of the other hand. A systolic bruit over the thyroid may be heard on auscultation.

Metabolism.—The thyroid gland controls metabolism, and the increased basal metabolic rate in thyrotoxicosis is a fundamental feature. Modern mechanical apparatus which records oxygen absorption permits the estimation in 10 minutes, and is a valuable arithmetical method of measuring the severity of the disease and its subsequent progress. There is a negative nitrogen balance, and excessive creatinuria indicates a pathological breakdown of muscle tissue. The fat depots of the body tend to disappear, and the serum cholesterol is low, *e.g.* 80 compared with normal 180.

The liver is depleted of glycogen, and transient or persistent glycosuria may appear. This rarely indicates true diabetes mellitus, which is not more common among thyrotoxic patients than among the rest of the population. Nevertheless, thyroxine is antagonistic to insulin. In thyrotoxic glycosuria, the resting blood sugar level is normal, but following 50 grams of glucose there is a high and prolonged blood sugar curve. In the absence of gastro-intestinal symptoms, or partial starvation, ketosis does not occur. There may be a negative calcium balance and, although the serum calcium is not raised, as in hyperparathyroidism, the renal excretion of calcium is not infrequently excessive. There results a decalcification of the bones, which rarely may reach a severe degree. The negative calcium balance is not apparently proportional to the basal metabolic rate, and is not always cured by thyroidectomy, even when the latter is otherwise successful. There is a negative iodine balance, with a raised blood iodine and increased urinary excretion of iodine. Unless iodine is given, the thyroid gland in thyrotoxicosis contains appreciably less iodine than the normal gland, because thyroxine is rapidly secreted and not stored.

Other features.—Relative impotence may be present in the male, and amenorrhœa or scanty menstruation is common in females. Pigmentation is not uncommon in the orbital region, but may be more diffuse. Premature whitening of the hair sometimes occurs. No characteristic blood changes are met with, but a lymphocytosis may be present. Crises are an alarming feature of thyrotoxicosis, sometimes precipitated by infection, or diarrhœa, but often apparently without cause. There is an acute exacerbation of the condition, with manifestations predominantly cardiac, cerebral, or gastro-intestinal, and the patient may die. Occasionally abdominal pain may be severe enough to simulate an acute abdomen, and on laparotomy acute congestion of the pancreas has been observed.

Diagnosis.—When the classical features of tachycardia, exophthalmos, enlarged thyroid, tremor of the hands, and loss of weight are present the diagnosis usually offers no difficulty, and a raised basal metabolic rate is confirmatory evidence.

" Masked " forms of hyperthyroidism, or " formes frustes," in which the presenting feature appears to indicate some other disease, may offer difficulty, but awareness of the possibility of hyperthyroidism usually prevents a mistaken diagnosis. Thus, cardiologists are always on the look out for a possible thyroid basis in cases of auricular fibrillation, and it would seem that the latter may occur in paroxysmal form before the clinical picture of hyper-

thyroidism is well developed, while occasionally fibrillation may supervene some years after the disease is apparently arrested.

I have been impressed by the number of patients with wasting as the presenting feature, the thyroid basis being undiagnosed for some time. In some of these cases, diabetes mellitus may be suspected, especially if glycosuria and hyperglycæmia are present; but, when the carbohydrate disturbance is due to thyrotoxicosis, the fasting blood sugar is not raised, and the glycosuria is often intermittent and independent of diet. The muscular wasting and weakness of hyperthyroidism may simulate the myopathies, or myasthenia gravis. The latter is an extremely rare complication of thyrotoxicosis, and is differentiated by the selectivity for groups of muscles and the response to prostigmine. Some patients are treated for an associated neurasthenia before the thyrotoxicosis is recognised. An overactive sympathetic nervous system at the climacteric may produce many features simulating thyrotoxicosis, but only a small proportion of such patients have a true thyrotoxicosis. Neuro-circulatory asthenia may simulate hyperthyroidism, and the thyroid gland is often somewhat enlarged, but in the former the tachycardia is more dependent upon emotion and change of position, and the pulse rate at rest or when sleeping is usually not raised.

Course and Prognosis.—The natural course of the disease, in the absence of treatment, is progressively downhill, but waves of remission and exacerbation occur. Nevertheless, some patients spontaneously recover, or even become myxœdematous. The chief dangers are cardiac failure, intercurrent infection, and mental disorder.

Treatment.—It should be noted that the treatment of Graves's disease is always medical, even although more often than not an essential part of treatment is surgical removal, or radiological destruction, of the greater part of the hyperactive thyroid gland. Some patients respond to medical treatment alone, and in early or mild cases this should always be given a fair trial. Rest and quiet, together with sedatives, are obvious indications. Quinine hydrobromide is sometimes used, in dosage of 10 gr. t.d.s., the thyrotoxic patient having an increased tolerance for this drug. It is usual to advise some form of psychotherapy, such as reassurance and suggestion, and, if the anxiety-neurotic symptoms are predominant, more specialised skill in this field may produce excellent results.

The diet should be a full one, and there are no grounds for curbing the patient's appetite except in so far as fatty foods may not be well tolerated, while rapid gulping of food results in discomfort. Catabolism of carbohydrate, protein and fat is excessive, and the body has need of their replacement. Insulin (*e.g.* 10 units t.d.s. after meals) may help to increase weight, and sometimes has a beneficial effect on the symptoms. Similar anabolic effects result from testosterone propionate, 50 mg. intramuscularly three times a week, but there is a danger of virilisation in the female if this therapy is prolonged. Cortical extract (cortin) or desoxycorticosterone acetate is also of some value. Fluids should be drunk freely to satisfy thirst, and in the presence of diarrhœa and vomiting it may be necessary to give saline and 5 per cent. dextrose by continuous drip intravenously, if rectal or subcutaneous methods prove inadequate.

It is usually held that iodine should be restricted to pre-operative use, since the patient becomes refractory or even worse after 2 weeks. In my experience,

however, small doses of iodine, such as 3 minims of Lugol's iodine once daily, may be continued for months or years with benefit. It is not curative, but it appears to enable the disease to run its course at a lower level of thyrotoxicosis and has a favourable influence on all the symptoms. The gland itself, however, may become larger and more tense as the vesicles become distended with colloid. Lugol's iodine is usually taken in an ounce or two of milk after a meal. It may be replaced by diiodotyrosine, 10 mg. or more daily, but this drug has no obvious advantage. Simple tachycardia is uninfluenced by digitalis, which should only be employed when the condition is complicated by auricular fibrillation or cardiac failure (see Heart section).

Sepsis frequently produces an exacerbation of thyrotoxicosis, and removal of septic foci an amelioration. Nevertheless, tonsillectomy or even dental extraction may be followed by a severe crisis endangering the life of the patient, and when the thyrotoxicosis is of any severity it is more prudent to resort to radiation or thyroidectomy before removing the septic foci. Pregnancy tends to aggravate thyrotoxicosis, although temporary benefit is sometimes observed; and the incidence of miscarriage, premature and stillbirths, is high. Thyroid radiation or thyroidectomy within the first few months is the best treatment.

Surgical Treatment.—When medical treatment has failed to control the disease, or in those cases in which the malady is advanced when first seen, and still more so when auricular fibrillation has supervened, there should be no undue delay before resorting to surgery. The worse the cardiac condition, the more urgent the need. It should be remembered that total thyroidectomy is sometimes advocated for cardiac insufficiency even in the absence of thyrotoxicosis; and that auricular fibrillation or cardiac failure associated with thyrotoxicosis tends to be refractory to digitalis or quinidine unless thyroidectomy is performed. The use of pre-operative iodine and the improvement in anæsthesia and surgical technique have reduced the mortality to 1 per cent.

Lugol's iodine is given in doses of 10 minims t.d.s. for 10 days before operation. Bromethol (avertin), 0·1 gram per kilo weight, preceded by morphia, $\frac{1}{8}$ gr., in nervous patients, is administered per rectum. The patient is usually drowsy or asleep after 30 minutes and can then be taken to the operating theatre. Gas and oxygen, but no ether, supplement the anæsthesia, and many surgeons also use local infiltration with 0·5 per cent procaine hydrochloride (novocaine). After operation, restlessness is controlled by sedatives by the mouth or per rectum. Morphine should be used sparingly, as cyanosis is best avoided. In the presence of cyanosis, or even merely with exacerbation of general symptoms, an oxygen tent or room is of great value. The Lugol's iodine is continued as before operation, and after a week the dose is gradually reduced to 5 minims daily, which is continued for 3 months. This is thought to prevent recurrence of thyrotoxicosis, but large doses of iodine may encourage the onset of myxœdema if the thyroidectomy has been extensive. The pulse rate and temperature are usually raised for some days after operation, after which there is a gradual return to normal. A crisis may, however, follow operation, with a rising pulse rate, gastro-intestinal symptoms, restlessness, and perhaps coma. Lugol's iodine must then be administered in large doses, *e.g.* 100 minims in 12 hours. If not retained by mouth, or by duodenal tube, or per rectum, it is given intravenously, in a

litre of saline and glucose, and it may even be better to use this route without delay. Auricular fibrillation may appear for the first time after operation, but frequently disappears spontaneously after a few days. If not, quinidine sulphate is employed, 3 grains on the first day, increasing up to 3 grains five times a day. If no effect after 40 grains, digitalis is given. If fibrillation is terminated by quinidine, the rhythm will frequently remain regular on discarding the quinidine (see also Cardiac Section). It is advisable for the patient to endeavour to lead a quiet, unworried life for some months after operation. Some 60 per cent. of patients are cured, and the remainder improved in varying degree.

Radiation.—Until the last 5 years the results in this field were variable, and complicated by skin burns. With the employment of deep X-ray, however, they are much better, and it may be that those of some technicians equal surgical results. Unless the case is of great severity or complicated by auricular fibrillation, in my opinion deep radiation is justifiable therapy, and is unlikely to interfere with subsequent surgery should such prove necessary.

Treatment by radium surface application or the insertion of radon seeds is not generally considered to be as efficacious, although advocated by some.

SECONDARY THYROTOXICOSIS

Synonyms.—Toxic Adenoma ; Nodular Goitre with Hyperthyroidism.

Definition.—Hypersecretion of the thyroid gland superimposed upon a previously symptomless goitre, or associated from the first with a clinically nodular goitre.

According to many observers there is no essential difference between Graves's disease and secondary thyrotoxicosis, either on clinical or morbid anatomical grounds. It is true that every grade of transition from one to the other is clinically met with, and that the pathologist is unable to say with certainty from a study of sections of thyroid glands to which clinical group it belongs. Small multiple adenomas occur in Graves's disease, and areas of hyperplasia said to be characteristic of Graves's disease may be present in nodular goitre. Nor is there any conclusive evidence in favour of Plummer's hypothesis that in Graves's disease there is a qualitative abnormal as well as excessive secretion by the thyroid gland, and that in toxic adenoma there is simply a quantitative hyperthyroidism.

Nevertheless, clinically the following points of differentiation from Graves's disease are worthy of note. Exophthalmos is absent, or only present in minor degree ; nervous excitability is less intense, associated anxiety neurosis uncommon, and psychosis extremely rare ; the brunt of the disease appears to fall on the cardio-vascular system and auricular fibrillation is more frequent, the latter fact being associated with the greater age incidence, since the majority of cases are over 40. The response to iodine may be inadequate in some 30 per cent. of cases, but the operative mortality is less than 1 per cent., and recurrence of thyrotoxicosis is rare.

The greater part of what has been written in the section on Graves's disease is applicable to toxic adenoma, but the need for surgery is much greater and little time should be lost on other methods of therapy. The

response to radiation is also less satisfactory than in Graves's disease. It is rarely possible to deal effectively with the auricular fibrillation, or cardiac insufficiency, of toxic adenoma prior to thyroidectomy, and the sooner the operation is performed the better.

With toxic adenoma, even more than with Graves's disease, there are masked forms in which the presenting features are cardio-vascular and the other constitutional symptoms slight. This is especially true in the case of elderly people, and some cardiologists urge the diagnosis of thyrotoxic auricular fibrillation in the presence of goitre even when the basal metabolic rate is normal.

MYXŒDEMA

Synonym.— Hypothyroidism.

Definition.— A primary condition of hypothyroidism, associated with low basal metabolism, and manifested by sensitivity to cold, mental hebetude, loss of hair, and mucoid infiltration of the skin and subcutaneous tissue. It does not include hypothyroidism secondary to pituitary hypofunction, as in Simmonds's cachexia.

Ætiology.—Myxœdema usually occurs sporadically and without obvious cause, although there is occasionally a history of preceding infection. It is more frequent in women than men, in the ratio of 8 to 1, and is most common in middle age. Perhaps the condition in women is comparable to the cessation of ovarian function, which also is met with in the fourth decade. The disease, however, may have its onset in old age, or even in childhood—when it is known as juvenile myxœdema. There would also appear to be a constitutional predisposition, as several cases in the same family may be met with. Myxœdema may follow partial thyroidectomy for thyrotoxicosis, or complete thyroidectomy for non-thyroid cardiac disease, the term cachexia strumipriva sometimes being given to post-operative myxœdema. Apart from operation or excessive radiation, myxœdema may spontaneously follow chronic thyrotoxicosis. Another group of myxœdematous cases occur endemically and usually with goitre, the ætiology being a relative or absolute iodine deficiency.

Pathology.—The thyroid is atrophic, and the secreting epithelium is largely replaced by fibrous tissue. The skin and subcutaneous tissue are infiltrated with a mucoid-like material, which was wrongly thought to be mucin, and hence the name myxœdema. There is an abnormal accumulation of extra-cellular and extra-vascular protein, the osmotic pressure of which leads to a transfer of saline from plasma to interstitial tissues. The mucoid infiltration may be widespread and implicate the nasal, pharyngeal, buccal and auditory mucous membrane, salivary glands, the larynx, and the œsophagus. The kidneys are sometimes extensively involved, and there may be deposits in the vulvo-vaginal region. The heart and coronary vessels not infrequently show atheromatous changes, with some cardiac dilatation, but contrary to general belief, actual mucoid infiltration is a rarity.

Symptoms.—The onset is usually insidious, and at least half the patients have had the disease for some years before it is recognised. The general condition is comparable to hibernation, all the physical, metabolic and mental processes being sluggish and reduced much below the normal.

Integument.—The facies is pale and puffy, with baggy eyelids and a characteristic malar flush. There is thinning of the outer half of the eyebrows, and the hair of the head is dry and lustreless and falls out, sometimes with resulting patchy alopecia. The skin is dry and rough, and gives a swollen œdematous appearance, especially in certain regions, *e.g.* face, neck, supraclavicular areas, hands, legs and feet; but there is no pitting on pressure. In contrast to hyperthyroidism, obvious sweating is minimal or absent.

Cardio-vascular.—The pulse rate is characteristically slow, *e.g.* 50, but there may be tachycardia with cardiac insufficiency. The blood pressure may be raised but not necessarily so. Angina sometimes occurs. Radiography usually shows enlargement of the heart, and the electrocardiogram a flattened or inverted T wave, etc. (see Cardiac Section).

Mental changes.—Apart from the psychoses, especially melancholia, which may complicate advanced or chronic cases, there are characteristic abnormalities of behaviour. The intellectual processes appear dimmed, and memory is poor. There is a noticeable latent period before questions are answered, and speech is slow, thick, indistinct and rather toneless. The whole attitude is apathetic and lethargic, with a tendency to somnolence.

Metabolic.—The basal metabolic rate is usually of the order of −40, the temperature is subnormal, and the patient hypersensitive to cold, being especially intolerant of the winter months. There is an almost constant hypercholesterolæmia, *e.g.* value of 400 mg. per cent., compared with a normal of 180; the cause of this is uncertain. The fasting blood sugar is frequently low, and the flat carbohydrate tolerance curve shows an apparently increased tolerance. Spontaneous hypoglycæmia is rare, but there is hypersensitivity to insulin. Occasionally the opposite condition of decreased carbohydrate tolerance is met with, but in these circumstances it would appear likely that there is a coincident atrophy of the pancreas.

Blood.—There are three types of anæmia found in myxœdema: (1) Hypochromic low colour index anæmia. This variety responds to iron. It differs from other iron deficiency anæmias, however, in the absence of microcytosis. (2) Hyperchromic megalocytic high colour index anæmia. This responds to liver, and is comparable to Addisonian anæmia. (3) Simple hypochromic macrocytic high colour index anæmia. It differs from Addisonian anæmia in the absence of megalocytosis and failure to respond to liver. Neither does it respond to iron, but thyroid has a specific effect, although a gradual one. The three types may be associated with achlorhydria, which is not uncommon, but type (3) is a specific thyroid deficiency anæmia. Either of the first two types may, on treatment with iron or liver respectively, change into the last type (simple hyperchromic). It is generally assumed that thyroid is a direct hæmopoietic agent essential for maturation of red cells, but the partial atrophy of the erythron in hypothyroidism may be an adaptation to the diminished need of the tissues for oxygen.

Other features.—Constipation is common, in contrast to the diarrhœa of thyrotoxicosis. Similarly, appetite and thirst are diminished. Deposits of mucoid material may impair hearing, smell, taste and swallowing. There may be amenorrhœa or menorrhagia, and in the male relative or absolute impotence is not infrequent. Vague generalised pains may be a feature, but it is difficult to conjecture a specific relationship.

Diagnosis.—Even though well-developed myxœdema presents a characteristic clinical picture, it is perhaps the most frequently missed endocrine disorder, and this is certainly true of the early or slight cases. The best method of avoiding this is to constantly bear in mind the existence of the disorder, especially when dealing with menopausal multipara. Sluggish mental response, with thick, dry skin and loss of hair, failure of memory, and sensitivity to cold are characteristic.

Many patients will first be seen by the psychiatrist, although the disease must have been present for some time. Others will present themselves to the gynæcologist on account of menorrhagia. Again, the appearance of the patient may lead to the diagnosis of anæmia, confirmed by blood examination, but the other features should not be missed. The pale, puffy face with baggy eyes also resembles the facies of parenchymatous nephritis, and albuminuria may complicate myxœdema if the kidneys are involved in the mucoid infiltration; a further resemblance between the two conditions is the high blood cholesterol. Myxœdema may be difficult to differentiate from hypothyroid features in Simmonds's cachexia (which see), both having a low B.M.R. and sensitivity to cold. In the latter condition, however, mucoid infiltration of the skin is rare, the skin being thin and wrinkled, and the patient has lost much weight.

Localised myxœdema may paradoxically be a complication of hyperthyroidism, usually in a recurrent or post-operative phase. The B.M.R. may have changed from above to below normal, but is sometimes still raised. Thick œdematous plaques appear on the front of the shins, or the whole leg may be thickened. The overlying skin is often wrinkled and hairy, and the skin may itch or burn. Nodular lesions may also involve the face, arms, back or scrotum. The pathogenesis of localised myxœdema is uncertain, for the response to thyroid is poor.

Course and Prognosis.—In the absence of specific treatment the course is slowly but progressively downhill, and many patients end in the asylum. The response to treatment, however, is usually excellent though by no means necessarily so if a psychosis has already developed.

Treatment.—The specific treatment in myxœdema is thyroid. The drug is best given in the form of thyroideum, B.P. The maintenance dose for the average patient is about 3 grains daily. It is, however, prudent to commence with smaller doses, *e.g.* 1 gr., especially because of the extra strain that may be thrown on the heart by the increase in metabolism and the rate of circulation. A heart that was previously adequate may be unable to meet the extra demand, and cardiac failure or even angina may supervene if the initial dosage is too large. In the long run, however, thyroid in appropriate dosage has a beneficial influence on the cardio-vascular system. If an untreated myxœdematous patient is first seen with some cardiac insufficiency and a rapid pulse (in contrast with the usual bradycardia), there may be hesitation to give thyroid; but in small and gradually increasing dosage the drug has a beneficial if paradoxical effect, the cardiac rate diminishing as the heart and coronary circulation improve. With the more usual bradycardia, thyroid has the effect of increasing the pulse rate, and should this rise above 76 the dose of thyroid should be reduced. More exact criteria of dosage may be obtained by estimations of the basal metabolic rate or the blood cholesterol. It is useful to remember that thyroid, even

if administered intravenously as a single dose of thyroxine, requires 24 to 48 hours to begin to act, has its maximum effect at the end of a week, and continues to act for several weeks. There is therefore no point in giving thyroid more often than once daily, and a cumulative effect may be guarded against by missing one week in four. Thyroxine has no advantage over the dried gland, and its intravenous administration is not without danger as the initial reaction may be alarming, *e.g.* nausea, vomiting, angina, pyrexia, aching muscles, loss of hair and peeling skin.

Dinitrophenol raises the basal metabolic rate to normal but has no beneficial effect on the symptoms, and is only of scientific interest. Pituitary thyrotrophin has no influence on myxœdema, since the thyroid is incapable of responding to such a stimulus. It has, however, a beneficial and specific effect in hypothyroidism secondary to pituitary hypofunction, but this does not persist for longer than 3 weeks, owing to the development of anti-thyrotrophic substances. It is therefore of no clinical value.

Hypochromic anæmia is treated with iron; simple hyperchromic anæmia with thyroid; Addisonian anæmia with liver. Whatever the appropriate indication, thyroid will not be withheld except for scientific investigation. If exact hæmopoietic investigation is not available, most anæmias met with in myxœdema will respond to iron and thyroid, true Addisonian anæmia being very rare.

CRETINISM

Definition.—This is a condition of hypothyroidism beginning in fœtal life. In contrast, childhood myxœdema is superimposed on a normal infancy. The disorder may occur endemically or, more rarely, sporadically.

Ætiology.—The endemic form occurs in goitrous areas, the mother usually having a goitre. Iodine deficiency of the soil and water, and other theories are discussed in the Goitre section. No cause for the sporadic form is known. The sex incidence in both varieties is about equal.

Pathology.—In the endemic form, the goitre is usually the nodular adenomatous variety (see Goitre). In the case of sporadic cretinism, a goitre is rare, the thyroid being atrophic, with flattened irregular epithelial cells, small alveoli, and connective tissue overgrowth.

Symptoms.—The untreated cretin is mentally deficient, apathetic and somnolent, and tends to lead a vegetative existence. All the processes and stepping stones of childhood development are retarded, the fontanelles remain open for years, centres of ossification appear late, and the epiphyses remain ununited for long periods. Growth, however, is always deficient and cretinism is a variety of dwarfism. The facies is characteristic, being pale and pasty, and having a thick skin, wrinkled forehead, a broad nose with depressed bridge and big nostrils, and thick lips separated by a protruding enlarged fissured tongue. The hair on the head is dry and scanty, and the eyebrows and eyelashes frequently deficient. The body is characterised by a protruding, pendulous abdomen, with umbilical hernia, supraclavicular pads of fats, and some degree of scoliosis and lordosis. The hands are spatulate, with square finger tips, and the limbs lack muscular tone. Deafness is not infrequent, and speech is often impaired. Genital development is always retarded, and ultimate sexual maturity a rarity. As in the case of myxœdema,

there is a low basal metabolic rate, subnormal temperature, sensitivity to cold, a low blood sugar, sensitivity to insulin, and constipation.

Course.—If untreated, cretins remain semi-idiots and incapable of self-sufficiency. Intercurrent infection in childhood or adolescence is a common termination.

Diagnosis.—To those who have seen the characteristic appearance, the diagnosis of cretinism rarely offers difficulty. In contrast, a Mongol has mongoloid eyes, with epicentric folds, a good skin and complexion, fine but profuse hair, and a restless, bright manner.

Treatment.—Prophylactic treatment in endemic areas consists of small doses of iodine (see Goitre).

Treatment of the individual patient is specific, namely thyroid. One to three grains daily of thyroideum, B.P. may be required, as judged by the general effects and the cardiac rate. If given in infancy or early childhood, an approximation to normal may be attained, but sometimes a harmless, apathetic idiot is merely changed into a mischievous, truculent semi-idiot.

GOITRE

Definition.—A goitre is a pathological enlargement of the thyroid gland, which may be endemic or sporadic, symptomless or associated with hyperthyroidism or hypothyroidism. The contour of the gland may be smooth or nodular.

Ætiology.—Endemic goitre occurs in many regions throughout the world, including certain areas in this country, *e.g.* Derbyshire and Somerset. In Switzerland, where earlier investigations were undertaken, one factor found to be common to goitrous regions was a deficiency of iodine in the water and soil. This is not always the case in other parts of the world, and goitrogenic agents in an infected water supply have been implicated, although the deleterious effect may be obviated if the iodine content of the water is higher. Vitamin deficiency and a preponderance of calcium over iodine are other possible factors.

The ætiology of sporadic goitre is obscure. Apart from a possible relative iodine deficiency, a familial predisposition is sometimes apparent. The increased demands of the body for thyroxine at puberty may be indicated by a transient physiological thyroid enlargement, but this sometimes persists as a puberty goitre. Endemic goitre is usually obvious in childhood, and its peak incidence is at puberty. This is also true of sporadic goitre, which may however be met with at all ages. The sex incidence of goitre is about equal in childhood, but, after puberty, females are more often affected than males—about 8 to 1.

Pathology.—The smooth diffuse goitres may be divided into the parenchymatous and the colloid, although both histological features are not infrequently present in the same gland. The parenchymatous goitres often show degenerative changes in the epithelial cells, and areas of fibrosis. The colloid goitres contain low cuboidal epithelium lining vesicles, filled with colloid. Nodular goitres usually contain multiple capsulated adenomas, which may show cystic or hæmorrhagic change. Occasionally there is a single adenoma, which may be of colloid type or of parenchymatous type. In the latter case,

it is thought by some to arise from solid masses of embryonic cells that may be seen in normal glands, and for this reason is termed "Foetal adenoma."

The above pathological changes occur both in endemic and sporadic goitres.

Symptoms.—When goitre is associated with hyperthyroidism, the symptoms may be those either of Graves's disease or of secondary thyrotoxicosis (which see). When associated with hypothyroidism, the clinical picture is that of cretinism or myxœdema.

In all varieties of goitre, including those which are endocrinologically inactive, pressure symptoms may be the major manifestations, especially so in the case of nodular goitres, and when goitres are low down in the neck or behind the sternum (intra-thoracic), pressure symptoms may be the only indication apart from that given by radiological examination. Pressure on the trachea may produce difficulty in breathing, irritating cough, alteration in voice, and stridor. For mechanical reasons, the dyspnœa is worse on lying down, and attacks of dyspnœa with cyanosis may be fatal. The voice is also affected by paralysis of the recurrent laryngeal nerve, this, however, being rarely bilateral. Pressure on veins may produce dilatation of those of the head and neck, with cyanosis, and in the case of intrathoracic goitre, dilated veins may be evident over the chest. Œsophageal pressure and resulting dysphagia are rare, as also are bradycardia due to vagus involvement, and mydriasis and sweating from cervical sympathetic stimulation.

Complications.—Malignant change is said to supervene in 1·6 per cent. of all goitres, and in 2·7 per cent. of nodular goitres. It is usually only after some years that malignancy develops, and clinical indications are a rapid increase in size and hardness of the goitre over a period of weeks or months, and sometimes with fixity to the trachea. In cases in which malignant changes supervene, 35 per cent. are correctly diagnosed before operation, 30 per cent. at operation, and the remainder only on histological examination. The capsule of the adenocarcinoma is frequently intact, but histology shows, in places, solid masses of columnar cells invading blood vessels. Occasionally a malignant goitre is so small as to be unsuspected, and the first sign is multiple metastases, especially in bones.

Course.—A goitre may remain symptomless and innocent throughout life, but at any time toxic symptoms of hyperthyroidism or hypothyroidism may become manifest.

Diagnosis.—This is usually obvious on inspection. Intra-thoracic goitre may be simulated by thymus or mediastinal tumours. Sometimes auricular fibrillation in a middle-aged or elderly person may draw attention to a small pre-existing goitre which has been symptomless for years. Pressure symptoms on the trachea may simulate asthma, perhaps with the complication of bronchitis, and some of these cases are not diagnosed for years.

Treatment.—In Switzerland the addition of iodine to all salt sold, 1 part in 100,000, has enormously reduced the incidence of endemic goitre; but in Derbyshire the results of a similar experiment have not been so convincing. In areas of endemic goitre in France, 1 minim of Lugol's iodine daily, has been employed, and in America iodised salt, 1 : 10,000, both with varying and on the whole satisfactory results. As might have been anticipated, the results are best if iodine has been administered to the mother throughout the pregnancy, but even when first given in childhood, the in-

cidence of goitre is considerably reduced. It is to be pointed out that in the case of symptomless endemic goitre, especially of the nodular variety, the use of iodine is not free from the danger of inducing thyrotoxicosis. This is also true in the case of sporadic goitre, although the writer believes that in simple diffuse goitre the risk is insignificant. At the same time, it is to be remembered that some symptomless endemic goitres become hyperactive apart from any treatment. Marine advocates, as an alternative to iodine, the use of thyroideum, B.P. 1 to 2 gr. daily, for simple sporadic goitre. This method of treatment, while logical and safe, is rarely curative.

Radiation therapy is beneficial in smooth goitres but less so in nodular ones. When in nodular goitre there are pressure symptoms or toxic manifestations, early operation is advisable.

If in goitre hypothyroid symptoms are present, thyroid is, of course, indicated. (See Cretinism, Myxœdema.)

S. L. Simpson.

DISEASES OF THE PARATHYROID GLANDS

The parathyroids are four in number, and are usually situated symmetrically in the posterior aspect of the thyroid gland. They secrete a hormone, parathormone, which gives protein colour reactions, is soluble in water and 80 per cent. alcohol, but insoluble in ether or acetone. The chief function of the glands is the regulation of calcium and phosphorus metabolism. Excess of the hormone leads to the clinical entity of osteitis fibrosa diffusa, and deficiency to tetany.

HYPERPARATHYROIDISM

Synonyms.—Generalised Osteititis Fibrosa Cystica; Von Recklinghausen's Osteitis Fibrosa; Osteitis Fibrosa Diffusa.

Definition.—A disease due to the excessive secretion of parathormone, and manifested clinically by hypercalcæmia, negative calcium balance, muscular atony, weakness and wasting, and decalcification of bones resulting in deformities and fractures.

Ætiology.—The disease, which is rare, is due to a neoplasm or hyperplasia of the parathyroid glands. The latter may be secondary to a pituitary stimulus, but parathyrotrophic hormone has not been demonstrated in the blood. The malady affects women twice as frequently as men. The average age incidence is about 40, but it also occurs in childhood and old age.

Pathology.—A circumscribed adenoma of one parathyroid gland is the commonest lesion, the remaining three glands being normal or hypoplastic. There may, however, be general hypertrophy and hyperplasia of all glands, which is usually obvious to the naked eye, and may even be of extreme degree, *e.g.* one weighing 5 grams compared with a normal of 60 mg. The cause of the hyperplasia is usually indeterminate; but occasionally it appears to be secondary to chronic renal disease and associated phosphorus retention. In the latter case there is a diffuse hyperplasia, without gross

enlargement, of the cells, whereas in idiopathic hyperplasia the cells are greatly enlarged and the cytoplasm is highly vacuolated. The essential skeletal changes are softening, replacement of bone marrow by fibrous tissue, rarefaction of the cortex, and the presence of numerous osteoclasts and osteoblasts, with osteoclastic giant cells and cyst formation. Deposits of calcium as fine granules may be present in all the viscera, especially the kidneys, lungs and arteries.

Symptoms.—These are all the direct or indirect result of excessive calcium mobilisation and excretion. The long bones may be bent and deformed, with perhaps osteoclastic tumours, and in some cases pathological fractures. The vertebrae are compressed, and not infrequently height is diminished by several inches. Osteoclastic swellings may deform the jaw. The shape of the skull is rarely distorted clinically. The bones and osteoclastomatous swellings are often tender, especially on pressure. The teeth are not decalcified. The muscles show atony, fatigueability, and atrophy. Gastro-intestinal symptoms are nausea, vomiting, constipation, abdominal pains and cramps. Polyuria and polydipsia are associated with the increased calcium excretion. Urinary symptoms are common. The calcium may be deposited diffusely, giving rise to the presence of chronic nephritis and renal insufficiency, or even multiple renal calculi, the latter consisting chiefly of calcium and phosphorus. Renal colic and pyelocystitis are complications.

Metabolic changes.—The calcium and phosphorus are mobilised from the bones, and excreted in excess in the urine and to a much less extent in the fæces. The serum calcium is usually raised, *e.g.* 15 mg. per cent. (normal 10 mg.), and the plasma phosphorus is diminished, *e.g.* 2 mg. per cent. (normal 3·5 mg.). In the presence of advanced renal disease, however, there may be phosphorus retention and a raised serum phosphorus. The plasma phosphatase is raised, *e.g.* 10 units compared with a normal of 2 units, and is a measure of osteoclastic activity. There is also an increased excretion of sodium and chloride.

Diagnosis.—Radiography shows generalised osteoporosis, with granular mottling in the skull. Rarely, bone changes may not be present until a later stage, and diagnosis may then depend on the raised serum calcium and increased urinary calcium excretion. In the absence of bone changes the serum phosphatase will not be raised. Some undoubted cases of primary hyperparathyroidism, cured by removal of a parathyroid adenoma, have had normal serum calcium values, but the urinary calcium has always been considerably increased. If the kidneys have been severely damaged by calcium deposition, the plasma phosphorus may be raised instead of being low.

When urinary symptoms are prominent, the underlying primary hyperparathyroidism may be unsuspected in the absence of metabolic investigation. Rarely, hyperparathyroidism of severe degree occurs secondary to chronic nephritis of long standing, and, in such patients, although the total urinary and fæcal calcium excretion is above normal, the serum calcium is normal or slightly less than normal and the phosphorus raised. Nevertheless, apart from the time sequence, ultimate diagnosis may depend upon histological examination of the parathyroid glands (see pathology above).

Gout and arthritis may be simulated, especially if there are tender deposits of calcium in the joints, and some patients are treated for vague

rheumatic pains or lumbago. In Paget's osteitis deformans, a disease of middle or old age, there is great deformity of the skull, normal calcium and phosphorus metabolism, but an increased serum phosphatase. Osteomalacia, or *adult* rickets, is very rare in England and America, and is due to deficient intake of vitamin D or lack of sunshine. The bones are soft and deformed, the plasma phosphatase is raised, and the plasma phosphorus is low, but the serum calcium is never above normal and is often below.

Albright has described a syndrome of multiple bone cysts and areas of rarefaction, segmentally distributed in relation to nerve roots, with corresponding patches of pigmentation. The disorder is found mostly in girls and in them is associated with sexual precocity, a feature not present in the male. There are no metabolic changes.

Prognosis.—In the absence of surgery, the course of the disease is progressive deterioration, and death occurs within a few years. Weakness, wasting and deformities compel the patient to take to bed. Intercurrent respiratory infection may terminate life, while others die from uræmia or pyelonephritis.

Treatment.—Primary hyperparathyroidism can only be adequately controlled by removal of a parathyroid adenoma or, in the case of hyperplasia, of two or more parathyroid glands. Deep radiation is usually ineffective, and a high calcium and phosphorus diet is only mildly beneficial and not without danger in the presence of renal insufficiency. If at operation no adenoma is discovered, the exploration should be continued above and below the thyroid region, behind the œsophagus and into the upper mediastinum, for a parathyroid tumour is sometimes found in such aberrant positions. Tetany, sometimes of severe degree, may occur within a few days after operation but is sometimes delayed for some weeks. It may be avoided by removing five-sixths of a large adenoma instead of the whole, the problem here being analogous to thyroidectomy in Graves's disease. If tetany does occur and can be controlled medically for a period of weeks or months, it often disappears completely, probably due to subsequent hyperplasia of the remaining parathyroid glands. The detailed treatment of tetany is discussed under that heading, but post-operative tetany is more logically treated by intravenous, intramuscular or oral calcium than by solution of parathyroid, U.S.P. (parathormone), as the bones are already dangerously decalcified. Following parathyroidectomy, the general symptoms, *e.g.* pains, weakness, anorexia, improve almost at once, but the bones may take several months to become normally calcified. The serum calcium immediately falls to normal or below normal, but the phosphatase tends to remain high for some months, being an indication of osteoblastic activity. The sudden change from high to low serum calcium may cause transitory visual and mental disturbances with some degree of apprehension.

HYPOPARATHYROIDISM

Synonym.—Parathyroid Tetany.

Definition.—A disease characterised by an irritability of the neuromuscular system due to a subnormal concentration of serum calcium, the latter being the result of deficient secretion of parathormone. All forms of

tetany are due to subnormal concentrations of calcium, or of ionised calcium, in the serum, but this is not necessarily the result of parathyroid hypofunction.

Ætiology.—Idiopathic hypoparathyroidism occurs sporadically, as does myxœdema, and may do so at any age, but it is a rarity. Most cases follow thyroidectomy when the surgeon has removed some or all of the parathyroid glands at the same time. Other cases follow removal of a parathyroid tumour and the remaining glands appear to be temporarily hypoplastic; or when two or more hyperplastic parathyroid glands are removed in osteitis fibrosa diffusa. Parathyroidectomised animals show decreased urinary phosphorus excretion and rise in plasma phosphorus before changes in calcium metabolism are apparent. Later, however, there is a fall in serum calcium and a decreased excretion of calcium, with resulting tetany which may be fatal. Parathormone injections will prevent or correct the initial changes in phosphorus metabolism and the later calcium ones. Tetany occurs in conditions other than hypoparathyroidism if the concentration of calcium in the blood falls below normal. Thus in rickets, osteomalacia and steatorrhœa there is a deficient absorption and utilisation of calcium. The increased demands for calcium in pregnancy and lactation may render a latent tetany manifest. Tetany may be found in alkalosis, the total serum calcium being normal, but the ionised fraction below normal; alkalosis may result from excessive vomiting, hysterical hyperpnœa, or alkaline medication.

Pathology.—In idiopathic hypoparathyroidism, the parathyroid glands may be atrophic; in post-operative parathyroid tetany, too much parathyroid tissue has been removed.

Symptoms.—Following thyroidectomy and parathyroidectomy, symptoms may appear within the first 48 hours or may be delayed weeks or months. There is often a general irritability, nervousness and apprehension in addition to weakness. Paræsthesias, and muscular cramps and stiffness are common in the hands, especially on the ulnar aspect, but may also occur in the feet. These symptoms may be followed by, or from the first be associated with, muscular contractions of the hands and feet, giving the classical picture of carpo-pedal spasm. The so-called obstetric hand is produced by flexion at the metacarpo-phalangeal joints, extension at the interphalangeal joints, and adduction of the thumb. Spasm of the laryngeal muscles may produce hoarseness and stridor, and, if the bronchial muscles are also involved, respiratory distress and cyanosis result, sometimes with fatal convulsions or coma. Tetanic muscular spasms are not infrequently painful and may cause the patient to cry out in distress.

In chronic cases, ectodermal defects become apparent, *e.g.* brittleness and ridging of the nails, loss of hair, transverse ridging of the decalcified teeth. Blurring of vision, perhaps leading to blindness, is due to opacity of the lens (cataract), and minor degrees of the latter may be detected by slit lamp technique even in the absence of ocular symptoms. Muscular spasm may involve ocular muscles.

Diagnosis.—Although in most cases diagnosis is obvious, mild degrees of hypoparathyroidism with general irritability, weakness and paræsthesias and only slight ectodermal deficiencies, may be unsuspected. The following classical signs may be of diagnostic value. Chvostek's is the production of contraction of facial muscles by tapping the facial nerve below the zygoma; Trousseau's is the production of carpal spasm by a sphygmomanometer band

on the arm at a pressure just above systolic ; Erb's is an exaggerated muscular contraction in response to minimal electrical stimuli. The failure to elicit one or more of these signs does not exclude the diagnosis. Biochemical evidence is often conclusive. In hypoparathyroidism the serum calcium is always below the normal value of 10 mg. per 100 c.c. (*e.g.* 6 mg.) and the plasma phosphorus is above the normal 3·5 mg. (*e.g.* 7 mg.) ; there is decreased urinary excretion of phosphorus and calcium. In a doubtful case, an experimental high phosphorus diet will depress the serum calcium and produce neuro-muscular symptoms, but this does not occur with normal parathyroids. It is interesting to note, however, that in cattle there is a form of tetany, which is the result of excessive phosphorus in the diet.

Treatment.—The logical treatment of hypoparathyroidism is solution of parathyroid, U.S.P. (parathormone), which acts by primarily increasing the excretion of urinary phosphorus and secondarily mobilising calcium from the bones and raising serum calcium. This form of treatment, however, has several disadvantages. Thus, it is useless in acute tetany because subcutaneous or intramuscular injections may take 8 or more hours to be effective and are variable in time and degrec of effect. While intravenous injection is quicker it takes a few hours to act and, moreover, by this route there is a danger of a protein shock like reaction in some patients. Four hourly injections of 1 c.c solution of parathyroid (20 units) intramuscularly or subcutaneously may, however, be effective after the initial latent period ; and, rarely, overdosage results in nausea, vomiting, diarrhœa, failing circulation, dehydration, increased viscosity of blood, coma and death. With controlled serum calcium estimations, however, overdosage is a rarity and it is more probable that 40 units daily may not be adequate to control the disorder. Even when solution of parathyroid is effective at first, a refractory state sets in after some weeks. The latter is probably not due to the production of anti-hormonic substances in the blood, as in the case of other hormones, but to local tissue immunity since an intravenous injection of solution of parathyroid may be still effective. Nevertheless, this refractory state renders prolonged therapy with solution of parathyroid an impracticable scheme.

The immediate treatment of acute tetany is the intravenous or intramuscular injection of calcium gluconate, 20 c.c. of a 10 per cent. solution, the effect being rapid and dramatic, but only lasting some hours. The injections must be administered slowly, but a little leakage from a vein has not the local deleterious effects of calcium chloride. It is obviously necessary to follow this emergency injection by large doses of calcium gluconate or lactate by mouth, *e.g.* 12 gms. daily in divided dosage. Calcium chloride is less pleasant to take, and in practice the theoretical value of the resulting acidosis is not appreciable. This is perhaps less true of the addition of 3 gms. of ammonium chloride, daily, in 1 gm. capsules. In many cases calcium gluconate or lactate by mouth is sufficient to control the tetany. If not, there should also be given vitamin D, which acts by increasing calcium absorption from the intestine and secondarily by increasing phosphorus excretion in the urine. The dosage of vitamin D, or calciferol, should be high ; 50,000 to 200,000 units daily may be required. In severe cases these measures may still be ineffective, and then a derivative of irradiated ergosterol, called dihydrotachysterol, or A.T. 10, is of great value. It is not antirachitic, probably because it also causes considerable excretion of phosphorus from the

urine, but it produces a great increase in calcium absorption from the intestine and a rise of serum calcium to normal or above normal. Like vitamin D it is of no use in emergency, the effect not being produced for some 24 to 48 hours. It is, however, cumulative in action, and the dosage should be controlled by periodic serum calcium estimations if hypercalcæmia (nausea, vomiting, calcium deposition in kidneys, albuminuria, etc.) is to be avoided. The urinary test of Sulkowitch is a useful indication of dosage, apart from serum calcium. The reagent consists of oxalic acid and ammonium oxalate in glacial acetic acid, and equal amounts of urine and reagent are mixed. If no precipitate occurs, the serum calcium is probably below 7·5 mg. per 100 c.c., as the renal threshold for calcium varies between 7·5 and 9; if there is a fine white cloud, the serum calcium values are probably normal, about 10; if the precipitate looks like milk, the values are pathologically high. Using this technique Albright gives 3 c.c. of dihydrotachysterol a day by mouth until calcium appears in the urine, after which 1 c.c., 3 to 5 times a week is usually adequate. Dihydrotachysterol is prepared in an oily solvent containing 5 mg. of the drug per c.c., and is administered by the oral route.

Diet in hypoparathyroidism is a matter of some controversy. High calcium diets (milk, cheese, egg yolk) have the serious disadvantage of also being high phosphorus diets. It is better, therefore, to have a normal diet, or preferably a low phosphorus diet, and supply the extra calcium as calcium lactate or gluconate. The keynote of a low phosphorus diet is to eat less of milk, cheese, egg-yolk, meat and nuts, and more of fruit, vegetables, carbohydrates, fats, and white of egg.

S. L. Simpson.

DISEASES OF THE SUPRARENAL GLANDS

The suprarenal glands consist of two parts, cortex and medulla, which are separate organs in the lower species. The cortex is of mesoblastic origin, while the medulla is ectodermal. The cortex is composed of lipoid containing epithelial cells, arranged from without inwards in three zones, zona glomerulosa, z. fasciculata and z. reticularis. The inner portion of the latter is characterised by brightly staining granules (pigment zone). The medullary cells have an affinity for chromic acid stains, and are termed chromaffin cells. The adrenal glands are supplied by sympathetic nerves from the splanchnic and coeliac ganglia, but they are cholinergic.

The medulla secretes adrenaline (orthodioxyphenylethanomethylamine), and although this substance is sympathomimetic and, on injection, can produce vasoconstriction, an increase of blood pressure, cardiac rate, blood sugar, and of the basal metabolic rate, and dilatation of the coronary arteries, and of the bronchial tubes, etc., the medulla is not essential to life, and in animals may be destroyed by cautery without obvious changes resulting. Further, it is even doubtful if there is a continuous secretion of adrenaline in normal circumstances, although certain that it is secreted under abnormal circumstances, *e.g.* exposure to severe cold, during fright or emotion, during infections, and in hypoglycæmia.

The adrenal cortex is essential to life, and bilateral adrenalectomy results in death within 7 to 10 days. The following hormones have been isolated from the cortex: androsterone (androgenic), œstrone, progesterone, corticosterone, and desoxycorticosterone. The last appears to be an essential life-saving hormone, and has been synthesised from cholesterol. Corticosterone has only a fraction of the activity of desoxycorticosterone but this also is life-maintaining. The other hormones have no such action. Their sex influence is manifested under certain pathological, or experimental, conditions, although whether so under normal conditions is less certain. It is thought that the androgenic hormone is secreted by special cells which constitute a broad inner zone at birth, but soon after undergo involution, although they may become hyperplastic in virilism and pseudo-hermaphroditism. The zone has been termed the androgenic zone, and stains deeply with the Ponceau-fuchsin dye.

The chief function of desoxycorticosterone is the regulation of sodium metabolism, with an associated influence on water balance, chloride and potassium metabolism. After bilateral adrenalectomy, there is an increased excretion of salt and water, with a retention of potassium, and a corresponding fall in the serum values for sodium and chlorine, and a rise in serum potassium. (The normal values are sodium 320, chlorine 355, potassium 20 mg. per 100 c.c.). There is also a shift of fluid from the plasma to the viscera, especially the liver, and the muscles. The blood becomes viscous, and the plasma volume is seriously decreased. Desoxycorticosterone injections will produce a return to normal. The action of desoxycorticosterone on carbohydrate metabolism is, however, feeble compared with that of cortical extract. The latter will completely correct the depletion of hepatic glycogen and fall of blood sugar that occur in the adrenalectomised animal. Corticosterone is even more potent than cortical extract in its influence on carbohydrate metabolism.

ADDISON'S DISEASE

Synonym.—Hypocorticalism.

Definition.—A disease due to destruction and hypofunction of the adrenal cortex, and manifested by pigmentation, weakness, myasthenia, anorexia, loss of weight and hypotension. It was first described by Thomas Addison in 1849.

Ætiology.—The disease is found among all races, and in all climates. Males and females are affected about equally. It is commonest between the ages of 20 and 40, and rare in childhood and old age. Tuberculosis is the most frequent cause, but any infection or toxicosis may be ætiological.

Pathology.—In the case of tuberculous lesions, both the medulla and cortex are usually destroyed, except for small islets of surviving tissue. The gland is replaced by fibro-caseous tuberculous tissue with areas of fibrosis, giant cells and lymphocytes. There may be associated tuberculosis elsewhere, rarely pulmonary. A history of gland or bone tuberculosis in childhood or in other members of the family is not uncommon. The next most frequent cause is atrophy of the cortex, of unknown origin, the medulla being scarcely

affected. The cortex is almost entirely replaced by connective tissue and dilated capillaries, with infiltration of lymphocytes, plasma cells and leucocytes. The picture is more like a toxic necrosis than a simple atrophy. Rare causes are syphilis, amyloid disease, hæmorrhage, infarction, and malignant growth. The last may apparently produce the disease even when it involves the sympathetic nerve supply only, and not the actual glands.

Symptoms.—Weakness, loss of appetite, loss of strength, and pigmentation are the usual presenting features.

The onset is often gradual. Occasionally the patient may not be seen by a physician before a grave crisis has developed. This is especially so when pigmentation is not a conspicuous feature, in which connection, it is to be noted that pigmentation may be even absent in fair-skinned people and in acute cases. Usually the patient complains of feeling not well in a vague sort of way. He (or she) may be languid, lacking in strength, and easily tired. Appetite is poor, and there may be a special aversion to fatty foods. In more severe insufficiency, nausea and even vomiting are distressing features, while abdominal pain, rarely sufficiently severe to simulate an acute abdomen, is occasionally present. Pain and tenderness may be limited to the loin region above and internal to the kidney, or pain may be referred to the scapula or shoulder region as the result of irritation of the diaphragm by the diseased suprarenal. The absence of any pain is quite compatible with the disease, and in fact is even more usual. Constipation is common, but there may be intermittent attacks of diarrhœa, either spontaneous or following purgatives, and these may precipitate a crisis. Hiccups and yawning are symptoms which may be very intractable, and which indicate incipient deterioration. There is progressive loss of weight, myasthenia and general weakness.

Generalised pigmentation, usually involving the mucous membranes as well as the skin, is a classical sign of the disease. The pigment deposited on the mucous membranes and skin is the normal pigment, melanin. Cutaneously, it is deposited in the basal layer of the epidermis, but in amounts greater than normal. Brown patches and streaks may be found on the inner aspects of the cheeks, the soft palate and posterior portion of the hard palate, the sides of the tongue, the gums, and the mucous surface of the lips, especially at the corners of the mouth. The distribution of skin pigmentation is partly determined by exposure to light and irritation. Thus, it is most marked on the face and neck, dorsum of the hands and forearms, waist-line, garter area, axillary folds and vulva, and in areas of skin overlying bony prominences, *e.g.* knuckles, ischial tuberosities and ankles. The palms show no evidence of increased pigmentation, except in the interphalangeal creases. Occasionally there are scattered cutaneous pigmented spots on the face and body. The nails of the hands and of the feet may be pigmented and striated. A leucodermic pattern of pigmentation is rare but authentic. Although pigmentation is a classical sign of Addison's disease, it may be inconspicuous or even absent in fair-skinned people, or when the onset is acute.

There is considerable variation as to interference with sex function. In some there is none, while in others there is amenorrhœa or impotence. Hypogonadism is certainly not an essential feature. Many patients feel the cold badly, especially in more severe insufficiency. The body temperature may be normal or subnormal, with perhaps intermittent pyrexia, and the basal

metabolism is rarely appreciably lowered, except in crisis. The systolic blood pressure is characteristically below 100 mm. of mercury, but this does not necessarily give rise to symptoms, and a normal blood pressure may persist for some time. Although in some patients the fasting blood sugar and carbohydrate tolerance curves may be normal, in others there is a chronically low blood sugar and clinical attacks of hypoglycæmia may even be fatal if unrelieved by glucose or adrenaline. There is an increased sensitivity to infections, shock, surgical trauma, hæmorrhage and drugs. Conjunctivitis is a minor manifestation, usually denoting inadequate therapy.

In crisis, the patient is collapsed, cold and restless. The latter feature may be intermittent, and stupor may be more characteristic. There is considerable irritability and intractability. The patient tends to curl up deep in the bed beneath the covering, and to resent interference. The pulse is rapid and of poor volume, and the blood pressure tends to fall acutely. Nausea, vomiting and diarrhœa may be persistent, thus adding to the dehydration that has resulted from the increased loss of salt and water through the kidneys. The veins are collapsed and the blood viscous on account of anhydræmia. Ultimately urine becomes scanty in amount, and terminally may contain casts and albumen.

Complications.—Addison's disease may be complicated by thyrotoxicosis or by diabetes but these are rarities. Other tuberculous lesions or intermittent infections, such as pneumonia, are not uncommon.

Diagnosis.—Clinically, this depends upon the classical features of pigmentation, weakness, wasting, anorexia and hypotension. Cutaneous pigmentation may also occur in other conditions, including hæmochromatosis, Hodgkin's disease, exophthalmic goitre, pernicious anæmia, arsenical poisoning, malignant cachexia, ochronosis, argyria, parasitic irritation, leucodermia and pregnancy. In Simmond's cachexia, a condition which has many features in common with Addison's disease, pigmentation is usually absent and is never diffuse, or marked. It is important to note that pigmentation of the mucous membranes is practically pathognomonic of Addison's disease. It is said by some to occur very rarely with pernicious anæmia, malignant cachexia and arsenical poisoning. Of the first, I wish to record that two authorities on pernicious anæmia have never met with pigmentation of the mucous membranes in this disease. In people of the negro race, or in those with an antecedent negroid admixture, pigmentation of the mucous membrane may occur normally.

If the serum sodium and chlorine are in low concentration (*e.g.* 295 and 330 compared with normal 320 and 355 mg. per 100 c.c. respectively), the diagnosis of Addison's disease is confirmed. Normal values at any one time on the other hand do not contraindicate the diagnosis. The serum potassium is rarely raised above the normal, 20 mg. per 100 c.c., except in an incipient crisis. A raised blood urea or low blood sugar is supporting evidence, but both of these may be normal. The Cutler diagnostic test consists in measuring the renal excretion of sodium chloride on a low salt diet, with the addition of potassium citrate in a daily dose of 42 mg. per pound body weight. On the first day, unrestricted fluids are given; on the second, 40 c.c. fluid per kilo body weight; and on the third, 20 c.c. per kilo body weight. The urine collected from 8 a.m. to 12 noon on the third day is assayed for chlorine. In

normal subjects an average of 50 mg. of chloride per 100 c.c. of urine is excreted, whereas in Addison's disease at least 200 mg. of chloride per 100 c.c. were excreted. The results, however, are not always so unequivocal, and Dryerre finds that the urinary sodium values are a better indication.

When tuberculous lesions of the adrenal glands have become calcified, radiology may be of diagnostic help by revealing calcareous shadows in the corto-vertebral angle.

Prognosis.—In the absence of treatment, there is progressive deterioration and death within months or years. With adequate substitution therapy, life may be prolonged, but the sensitivity to intercurrent infection is always a danger. Occasionally there is a spontaneous recovery sufficient to permit the cessation of substitution therapy.

Treatment.—As in other hormone deficiencies, the essential treatment is substitution. Until recently cortical extract (cortin, eucortone, eschatin) was employed, usually by intramuscular injection, and the daily dosage varied between 5 c.c. and 20 c.c. The most severe cases, however, required 30 c.c. or even 40 c.c. daily, and in these circumstances cost and mechanical difficulties rendered the maintenance of life precarious and painful. The cortin was standardised on adrenalectomised dogs or rats. A considerable advance was made by Loeb's discovery of the value of salt therapy. The dosage of sodium chloride is 3 teaspoonfuls, or some 12 grams, daily, taken in water, milk, porridge, or lime-juice, according to taste. In some patients the salt treatment produces nausea and vomiting as in the case of normal people, so that it must be discontinued, but others can tolerate it quite well. Mild cases need no other special treatment, but in the more severe cases cortin must be administered as well, though the salt permits a reduction in the dosage of cortin.

More recently Reichstein has isolated from the adrenal cortex and also synthesised from cholesterol a substance called desoxycorticosterone, which appears to be an essential hormone of the adrenal cortex. It is prepared in ampoules of 5 mg. in 1 c.c. sesame or arachis oil (doca, percortin, cortiron), and is injected intramuscularly. It would appear that 5 mg. of desoxycorticosterone is equivalent to 10 or more c.c. of cortical extract, and the acetate of desoxycorticosterone is normally employed for a more gradual action. Usually the injections are painless but some patients react with red hot lumps at the site of injections, and owing to a local tissue immunity they fail to do well with the synthetic hormone. There are, however, alternative methods of using desoxycorticosterone acetate. Thus, 100 mg. tablets may be inserted in the subcutaneous fat, under local anæsthesia. Four to 8 such tablets are necessary, according to the severity of the disorder, and the effect lasts from 4 to 6 months, or even longer, and the treatment may then be repeated. The tablets are sterilised at 100° C. in an autoclave. Desoxycorticosterone acetate is also effective by cutaneous inunction when dissolved in benzyl alcohol (20 mg. in 1 c.c. being equivalent to 5 mg. by injection), but this preparation is not yet on the market. Whatever route of administration of desoxycorticosterone is employed, cases are occasionally met with in which the response to treatment does not appear to be as satisfactory as with cortical extract. In such cases, the latter should be used instead of, or as supplementary to, desoxycorticosterone therapy. Whether cortical

extract or desoxycorticosterone acetate is used, it is important to remember that infection always calls for increased dosage. This is also true of the inserted subcutaneous tablets, since the rate of absorption does not vary with needs, but depends upon physical laws. It is doubtful whether a low potassium diet is worth the bother of preparation, although some report favourable results.

In crisis the treatment is on similar lines but more intensified. Thus, 20 c.c. cortin or 10 mg. desoxycorticosterone acetate would be given intramuscularly every 4 hours. It is rarely necessary to administer intravenous saline and dextrose, as was previously advocated, and, moreover, this procedure is not infrequently followed by allergic reactions and rigors. If, however, the patient is "in extremis," it is justified and such risk may be taken. Rectal saline by drop method is an adjuvant but not essential.

The treatment of the underlying tuberculosis, when the presence of such is established, is carried out on general lines, but the writer has not seen appreciable benefit resulting from tuberculin injections. Injections of the adrenotrophic hormone of the pituitary gland have been advocated, but here too the writer's experience has not been favourable. A graft of the adrenal glands of an infant, born dead because of mechanical difficulties and from healthy parents, can be effectively grafted into the rectus abdominis. If the graft is successful, beneficial effect will result, but the glands are gradually absorbed and rarely does the benefit last more than 6 months. It is not a method of treatment which can rival modern chemical therapy.

ACUTE SUPRARENAL DEFICIENCY

Apart from Addison's disease, there is some clinical and pathological evidence that acute adrenal insufficiency occurs with certain infections, such as meningococcal septicæmia, diphtheria, typhoid fever, and pneumonia. At autopsy, the suprarenals may show congestion, œdema, hæmorrhage, and necrosis. The onset is sudden. Malaise, restlessness, headache, vomiting, fever, cyanosis, scattered petechæ, and stupor or coma, are characteristic features of the malady. When the underlying lesion is acute bilateral suprarenal hæmorrhage, the term Waterhouse-Friderichsen syndrome has been applied to the clinical condition. This syndrome is usually associated with meningococcal septicæmia, and is more frequently met with in infants than in adults.

Acute suprarenal insufficiency may also complicate surgical shock and severe burns, the biochemical changes in the blood resembling those found in the more severe phases of Addison's disease.

Diagnosis.—The diagnosis of acute suprarenal insufficiency as a complication of infections, surgical shock, and burns, is often a matter of assumption, based on experimental evidence. That of the Waterhouse-Friderichsen syndrome is only occasionally made in life.

Treatment.—Treatment is similar to that described for Addison's disease, and there is some evidence that crude extract of suprarenal gland is more efficient than the synthetic desoxycorticosterone. Experimentally, the synthetic hormone corticosterone is of greater value than desoxycorticosterone.

HYPERCORTICALISM

In speaking of hypersecretion of the adrenal cortex one usually refers to hypersecretion of those cells concerned with sex function, but in some types of sexual precocity the abnormal muscular strength of the individual suggests also a hypersecretion of the life-maintaining hormone desoxycorticosterone. The sex hormones elaborated by the adrenal cortex in hypercorticalism are androgenic and œstrogenic hormones. The clinical conditions resulting are virilism, feminisation, pseudo-hermaphroditism and sexual precocity. The pathological basis is neoplasm or hyperplasia of the adrenal cortex, but in the two last conditions the hyperplasia may be a concomitant rather than a primary cause. As sexual precocity is frequently due to causes other than adrenal cortical hyperfunction it is considered in the gonad section.

VIRILISM

Synonym.—Adreno-genital Syndrome ; Cushing's Syndrome (part of).

Definition.—Virilism is said to occur when a female at any time after puberty fails to menstruate and also develops a male distribution of hair. Adiposity is often a third feature of the triad of the adreno-genital syndrome. (For Cushing's syndrome, see Pituitary Section.)

Ætiology.—The immediate cause is hypersecretion of androgenic hormone by the adrenal cortex. There appears to be a greater incidence among Jewish and Mediterranean people. There is, however, no sharp dividing line between milder cases of the disorder and accepted normality.

Pathology.—The lesion is an adenoma, a carcinoma, or a bilateral hyperplasia of the adrenal cortex. The cells have an affinity for the ponceau-fuchsin stain, and are thought to arise from the inner androgenic zone of the cortex. There is also a general lymphoid hyperplasia, and a large thymus. The ovaries tend to be atrophic.

Symptoms.—The changes usually begin at or soon after puberty, but may not become prominent until the late teens, or sometimes in the twenties, or later. The essential feature is an excessive growth of hair on the side of the face, the upper lip and chin, the forearms, thighs and legs and on the trunk. The last may be only slightly affected in the form of a linear growth of hair extending from the usual feminine horizontal upper limit of pubic hair upwards along the linea alba to the umbilicus; or the hair may cover the abdomen and chest, and tufts of hair surround the nipples. Menstruation may cease altogether, or may be only scanty and at long intervals. Sometimes menstruation is normal in the presence of a high degree of hirsutism, but such cases do not strictly come within our definition. The uterus may become small or may fail to develop, but more usually there is no gross change in its size. The clitoris may be normal or appreciably enlarged, sometimes resembling a small penis. The breasts may be atrophic or undeveloped, but with adiposity this fact is obscured. An increase of weight due to adiposity is usual, fat being deposited on the face and neck, breasts, abdomen and pubis, and upper parts of the arms and thighs ; the legs and forearms may be quite thin and graceful. There is a group of cases character-

ised by absence of fat, and with considerable muscular development and strength, and broad shoulders and narrow hips, as in the masculine build.

There may be other features approximating to the Cushing syndrome (which see), and intermediate types are met with.

Complications.—Some degree of pigmentation around the eyes is common and less frequently other features of Addison's disease are met with, while even death from adrenal insufficiency has been recorded. It would appear that hyperplasia of the "sex cells" in the adrenal cortex encroaches upon and destroys the cells that secrete desoxycorticosterone. Psycho-neurosis and psychosis, with loss of heterosexual desire and homosexual tendencies, may be complications. A complete feminine mentality, however, may be associated with virilism, and the fear of sex conversion and of feminine inadequacy is poignant.

Diagnosis.—A combination of hirsutism and amenorrhœa makes diagnosis obvious. A tumour should be suspected if the disease has started after the twenties in a person hitherto quite normal, and in no case can be excluded without investigation. Considerable enlargement of the clitoris is more common with a tumour, but may be present with hyperplasia. Intravenous injection of uroselectan combined with radiography may demonstrate a neoplasm. A more certain method, though not without danger, is perirenal insufflation of 450 c.c. of air, the neoplasm being shown surrounded by air in the radiogram. Ovarian tumours (arrhenoblastoma) may produce virilism; they are not always palpable on vaginal examination, and may be revealed by laparotomy.

Androgenic hormone is usually secreted in excess in virilism. Normally some 40 international units per diem are found in the urine, but with an adrenal tumour ten times this amount may be present. It is rare, but not unknown, for such large amounts to be met with in hyperplasia; more commonly, however, 100 to 150 units are present. The assay is done by measuring comb growth enlargement in injected capons.

Prognosis.—In the case of hyperplasia the condition may be stationary or only slightly progressive for many years. Sterility is the rule, but one child may be born. The successful removal of an innocent tumour may produce a reversion to normal. Carcinoma of the adrenal cortex is very malignant, and metastases or recurrences are the rule.

Treatment.—A tumour should be removed surgically. It is important to give cortin or desoxycorticosterone for a few days before and after the operation, since the opposite adrenal may be atrophic and the patient may die from acute adrenal insufficiency before this adrenal has had time to undergo hypertrophy. For bilateral hyperplasia, unilateral adrenalectomy is advocated, but although the operation may be followed by some return of menstruation it is, in the writer's experience, rare for the hirsutism or the adiposity to be appreciably affected. Large doses of œstrin by injection or by local inunction have been indicated, but here too the writer's experience is disappointing. X-ray treatment of the hirsutism has various disadvantages (burns, scars). This is less true of electrolysis, which may be helpful.

There are many instances of hirsutism without any disturbance of menstruation. In such cases, also, it is very important to try and give some philosophical or psychological comfort, though not an easy task. Since in actual fact we are here dealing with a variety of normality, it is to be

wondered to what degree intersexuality will ultimately be commonly accepted by the non-medical world. It is, after all, a reality.

FEMINISATION

This condition is a rarity compared with virilism. It is due to a tumour of the adrenal cortex in the male, usually malignant. There is a loss of libido and sexual potency, with a general increase in fat deposition and a hyperplasia of the glandular tissue of the breasts. The latter become enlarged, the nipples pigmented and the superficial veins dilated. There may even be some secretion, which can be expressed from the nipples as in incipient lactation. The patient usually dies from malignant metastases, but in one case successful removal of the tumour led to a return to normality. The testes on section show atrophy.

PSEUDO-HERMAPHRODITISM

Definition.—Pseudo-hermaphroditism is a condition in which there is only one type of gonad, testis or ovary, but in which the external genitals are a mixed representation of male and female characteristics, or characteristic of the opposite sex to the gonads. Strictly the term should be applied only to those cases in which the condition is present from birth, and not to those instances of virilism or feminisation which appear in later life. It is also not intended to include under this heading sexual precocity in the female due to an adrenal tumour and associated with hirsutism. Classification according to the type of gonad is the simplest, *i.e.* testicular pseudo-hermaphroditism and ovarian pseudo-hermaphroditism.

Ætiology and Pathology.—Gross hyperplasia of the adrenal cortex occurs in only 14 per cent. of pseudo-hermaphrodites, but it may well be that hyperplasia of the sex cells (androgenic zone) could be detected in a far greater proportion by the ponceau-fuchsin stain. It is certainly possible to produce symptoms of pseudo-hermaphroditism in the experimental animal (rat, guinea-pig, fish) by injecting large doses of androgens or œstrogens into the young animal or into the pregnant mother. Nevertheless, it is probable that the hyperfunction of the adrenal cortex is a mechanism, essential or concomitant, but primarily determined by genetic or chromosomal factors.

The seminiferous tubules are not completely developed, and spermatogenesis is usually absent, but the interstitial cells may be normal or hyperplastic. The ovaries are hypoplastic, fibrotic or cystic.

Symptoms.—(A) Testicular Pseudo-hermaphroditism.—The commonest and most easily understood type is the male in whom the formation of the external genitals is incomplete, the two scrotal folds remaining ununited (cf. hare lip), and enclosing a vagina-like cavity, one or more inches in depth. The penis may be incomplete, or hypospadias of varying degree may be present, or the penis may be so inadequately developed as to represent a clitoris. The patient is then brought up as a girl, until the appearance of masculine hair at puberty and the failure to menstruate lead to further investigation. The vagina is found to be false, the uterus absent, and the gonads testicles. The last, being retained in the abdomen, have the char-

acteristics of cryptorchid testicles, namely, absence or destruction of the spermatic tubules, and increase in the interstitial cells. Nevertheless, the secretion of male hormone may be deficient, and the patient be of eunuchoid type. Chapple has described the case of a young, beautiful woman, with no hirsutism, with a female figure, well-developed breasts, and normal feminine libido, who in spite of a short vagina had satisfying intercourse with males. She came under observation for painful lumps in the groin, which were found to be testicles. No uterus could be detected. It is more usual, however, for the testicular pseudo-hermaphrodite to have hirsutism and other secondary male sexual characteristics. Although the testis secretes as much œstrone as the ovary (and the female about as much testicular hormone as the male), it is difficult to understand why, of two pseudo-hermaphrodites with testes and female external genitals, one should have male hair and bodily form, and another be a beautiful female. Obviously the genetic factors may be more important than the endocrine. As regards the sexual organs other than the gonads there is a considerable variation, with the following possibilities in the case of a testicular pseudo-hermaphrodite: hypospadias only; with a vagina; with a vagina and Fallopian tubes; with a vagina, uterus and tubes. The testes may be in the pelvis, the inguinal canals, the labia, or in the scrotum.

(B) Ovarian Pseudo-hermaphroditism.—The female pseudo-hermaphrodite possesses ovaries, but has a masculine configuration, with the external genitals simulating those of the male. The basis of the condition is difficult to explain unless it is assumed that it is comparable to the adrenal virilism of the adult, and due to hyperfunction of the adrenal cortex commencing in fœtal life. Although to be within our definition such cases should show abnormalities at birth, these may not be gross until later childhood and may be further accentuated at puberty. The psychic and sexual behaviour of the pseudo-hermaphrodite varies in different individuals, and is often independent of the physical or endocrine basis. Thus the hirsute, testicular pseudo-hermaphrodite may be essentially feminine in outlook and libido, and capable of functioning to complete satisfaction of herself and partner in coitus. Some are ambisexual. Apart from indisputable pseudo-hermaphrodites, it is obvious that a number of people have the physical characteristics (apart from genitals), emotional reactions and libido of the opposite sex.

Diagnosis.—The recognition of the condition of pseudo-hermaphroditism is not difficult, although it may not become evident to the lay person until late childhood or puberty. The elucidation of the underlying pathology may, however, be impossible unless laparotomy is undertaken. Many patients present themselves with lumps in the inguinal canal, and it is only after removal and section of these gonads that the real sex can be determined.

Prognosis.—From the nature of the disorder it is unreasonable to expect a fundamental improvement, with or without treatment. The latter may ameliorate the condition.

Treatment.—If help is not sought before adult life, treatment should depend upon the sexual inclinations of the patient. If these are female, the clitoris should be amputated and, if necessary, the vagina enlarged. The removal of testes will diminish the hirsutism. In the child the removal of testes would prevent hirsutism, but in view of some testicular pseudo-hermaphrodites having beautiful feminine configuration without hirsutism

and the fact that the testis does secrete œstrogens, it is considered by some better to wait until puberty gives an indication of what is likely to develop. When the outlook and libido are masculine, a plastic operation can repair or create a scrotum and abolish the hypospadias. With ovarian pseudo-hermaphroditism the question of unilateral adrenalectomy arises, or the more drastic procedure of two-thirds resection of both adrenal glands. Good results have been reported, but the value of the procedure is still *sub judice*. Laparotomy may reveal that an apparent instance of pseudo-hermaphroditism was in fact the rarer condition of true hermaphroditism. Experience shows that it is unwise to speculate too much in the absence of laparotomy.

HERMAPHRODITISM

True hermaphrodites have both male and female gonads, namely, one testis and one ovary, or an ovo-testis in one organ. They are extremely rare, and it is probable that up to the present time not more than 20 cases have been described. Hermaphroditism is normal for some of the lower species, *e.g.* the worm, and is not a rarity among pigs and goats. In the hen, the right gonad is rudimentary, but if the left ovary is removed the right gonad becomes a testis and the hen grows a comb. Further, any remnant of the left ovary that is left behind may grow into testicular tissue, since the medulla of the ovary is the homologue of the testis. The change of sex in the hen may be so complete that the mother of chicks may become the father of chicks. In man the external genitals may give no indication of the internal genitals. Young, in 1933, described what he regarded as the twelfth case of true hermaphroditism on record. A young "male," tall and athletic, with penis and scrotum, and masculine hair, came to operation for undescended left "testicle." On opening the left inguinal canal, it was found to contain a uterus, Fallopian tube and functionary ovary. A portion of the right gonad in the scrotum was excised, and a section showed normal testicular tissue.

Although the adrenal cortex is frequently hyperplastic in true hermaphroditism, there is no evidence that this is the principal ætiological factor. On the contrary, the cause of true hermaphroditism would appear to be genetic, and the inherent mechanism gonadal. The importance of the genetic factor is well illustrated by the bullfinch, which may have a testis on the right and an ovary on the left, with masculine plumage on the right half of the body and feminine plumage on the left half. Huggins, Cohen and Harden reported another type of true hermaphroditism in which the patient was brought up and behaved as a woman, and one gonad was a testis and the other an ovo-testis, both removed from the inguinal canal and examined histologically. The patient was athletic and slightly hirsute. She had a normal vagina and uterus, and began to menstruate at the age of 14, at which time the clitoris became grossly enlarged and assumed the size of a small penis.

TUMOURS

Tumours of the cortex and of the medulla of the suprarenal gland are met with. They may be benign or malignant. Endocrine manifestations

are usual but not invariable. Tumours of the adrenal cortex may produce virilism, or the complete Cushing's syndrome (see above).

Tumours arising from the chromaffin cell of the suprarenal medulla are termed phæochromocytomas or paragangliomas. Such a tumour contains large quantities of adrenaline, and the latter is secreted into the blood paroxysmally, producing hypertensive crises. Thus, a previously healthy young adult may develop attacks of hypertension, palpitation, pallor, nausea, vomiting and cyanosis of the extremities; the systolic blood pressure may rise from 130 to 300 mm. of mercury, the change in the diastolic usually being much smaller. During the temporary rise of blood pressure, the patient may complain of agonising headache, and a sense of constriction in the chest with, perhaps, angina-like pain. There may be transitory hyperglycæmia and glycosuria, and albuminuria. The pallor and coldness of the skin, especially of the extremities, may be associated with, or followed by, profuse perspiration. Shivering, cramps of the calf muscles, mydriasis and pyrexia are other features.

These paroxysmal attacks may recur at increasingly frequent intervals, and the symptoms of hyperadrenalism may persist in lesser degree between the paroxysms.

Hypertrophy and degeneration of the arterioles are found in the more chronic cases, and the kidneys may show ischæmic fibrosis.

Removal of a medullary tumour will result in abolishing the symptoms, if the operation is done early enough.

Occasionally, bilateral tumours are met with.

THE SEX GLANDS

The testis secretes a hormone, testosterone, which has been isolated and synthesised, and is available commercially for substitution therapy. It is excreted in the urine in a slightly modified form, as androsterone. The ovary secretes two hormones, œstradiol and progesterone. The former can be obtained from ovarian follicular fluid, and the latter from the corpus luteum. Both hormones have been isolated and synthesised, and are available commercially for substitution therapy. Œstradiol is excreted in the urine as œstrone, and progesterone is excreted as pregnandiol. The action of both testosterone and œstradiol is prolonged by their esterification, so that, in practice, the propionate and benzoate respectively are employed. It is to be remembered that the sex hormones do not stimulate the gonads to increased activity, but they produce the same hormonal effects as the normal gonads do. Thus, testosterone produces increased libido, penile erections, growth of the immature penis and of the scrotum and prostate, hair on the face, and deepening of the voice. Œstradiol therapy results in growth of the mammary duct tissue, and a proliferative hyperplasia of the uterine mucous membrane. Progesterone has a further effect on the uterus, producing a secretory, or pre-gestational, mucous membrane. It thus prepares the uterus for the imbedding of the fertilised ovum, and therefore a deficient secretion results in sterility, or abortion. Progesterone also

reduces the hypersensitivity of the uterus to the posterior pituitary stimulus to uterine contraction.

The failure of gonadal function may be primary, or secondary to pituitary insufficiency. It has already been noted (see Pituitary Section) that there are two pituitary, or pituitary-like, gonadotrophins, A and B. The former stimulates the seminiferous tubules of the testis, and produces follicle maturation in the ovary. The latter acts on the interstitial cells of the testis, and produces luteinisation of the ovarian follicles. These physiological effects can be demonstrated in rats and rabbits, but not in man. Nevertheless, such experimental results constitute the basis of therapy.

THERAPEUTICS OF TESTOSTERONE PROPIONATE

The preparation may be given intramuscularly, the dose being 25 to 50 mg., three times a week. It may also be administered by inunction, the dosage by this route being four times as much.

A.—IN THE MALE

1. Eunuchism and Eunuchoidism.—Testosterone propionate will produce an increase in the size of the penis, scrotum and prostate, increased libido, and increased growth of hair on the face, on the pubis, and in the axillæ. Potency will be restored to normal. In the complete castrate, however, there is little or no ejaculatory fluid at the time of the orgasm, and spermatozoa are absent. There is a gain in muscular strength and weight; and a retention of fluid and of nitrogen.

2. Impotence.—In the majority of cases, impotence is psychogenic and does not respond well to testosterone therapy. The latter, however, is very effective in organic hypogonadism.

3. Male Climacteric.—The existence of a male climacteric is not generally accepted. Nevertheless, some men over fifty do complain of hot flushes, anxiety, inability to concentrate, and loss of libido, and all these symptoms may disappear with testosterone therapy.

4. Enlarged Prostate.—Testosterone has no effect on the objective signs produced by an enlarged prostate, but it does appear to ameliorate symptoms. Such benefit, however, has also been obtained by injections of inert oil.

B.—IN THE FEMALE

Testosterone propionate has been used with success in menorrhagia, with or without fibroids, in chronic mastitis, and also to stop lactation. If the therapy is continued for more than a few weeks, it may result in a growth of hair on the face, deepening of the voice, enlargement of the clitoris, and acne. These untoward effects tend to disappear after ceasing therapy.

THERAPEUTICS OF ŒSTRADIOL BENZOATE

This may be administered in the form of intramuscular injections of 1 c.c., containing 50,000 units, twice weekly, or as tablets by mouth, 1000 to 10,000 units daily, or by inunction.

1. AMENORRHŒA.—In primary amenorrhœa, uterine bleeding may be produced by one million units, given over a period of 4 weeks, and repeated if necessary. The effect is more physiological if the œstradiol is followed by 20 mg. progesterone. The resulting menstruation, or pseudo-menstruation, will not recur if therapy ceases. In secondary amenorrhœa, or in scanty menstruation, the normal rhythm and quality of menstruation may be restored after a few months' therapy, and may then continue normally without further treatment.

2. DYSMENORRHŒA.—When this is due to poor development of the uterine musculature, œstradiol benzoate may be beneficial. It is best prescribed in the first 2 weeks after each menstruation.

3. STERILITY.—Œstradiol benzoate will cause an infantile uterine musculature to develop. It also produces hypertrophy of the Fallopian tubes, and increases the patency of these tubes when they have been previously occluded. Pregnancy may follow such treatment.

4. CLIMACTERIC.—The climacteric in the female is a definite clinical entity, of which the menopause is only one feature. Although the constitutional disturbance in some patients is negligible, others suffer from nervousness, anxiety, hot flushes, general pruritus, pruritus vulvæ, vulval kraurosis and other symptoms. Œstradiol benzoate has a remarkable beneficial effect, but it may be necessary to continue this specific therapy over a period of months or years. The dosage varies with different individuals, and may be as little as 1000 units daily, or as much as 50,000 units daily.

THERAPEUTICS OF PROGESTERONE

1. ABORTION.—Progesterone may be administered prophylactically during the first 4 months of pregnancy, 5 mg. twice weekly by intramuscular injection. In threatened abortion, 5 mg. is given daily until all bleeding has stopped, and then twice weekly.

2. MENORRHAGIA.—Progesterone is sometimes useful in menorrhagia, 5 mg. being given daily for 5 days before menstruation is anticipated. It can also be administered during the bleeding if the latter is severe or unduly prolonged.

THERAPEUTICS OF GONADOTROPHINS

1. UNDESCENDED TESTICLE.—If there is no mechanical obstruction to the descent of the testicles, this condition will respond to gonadotrophin B. The dose is 500 units twice weekly, for 2 to 3 months. Since a large proportion of undescended testes migrate to the scrotum spontaneously at puberty, therapy is often delayed until the age of 11 years. Some children, however, develop an inferiority complex if the condition is left untreated.

2. MALE STERILITY.—If spermatozoa are absent or scarce, gonadotrophin A sometimes increases their number, but it is rare for fertility to result.

3. MENORRHAGIA.—Menorrhagia, especially at puberty or at the climacteric, may respond to gonadotrophin B, 500 units given twice weekly, or, if the condition is severe, daily.

HORMONE TESTS FOR PREGNANCY

The Ascheim-Zondek test and its Friedman modification depend upon the fact that there is a large amount of luteinising gonadotrophic hormone in the urine of pregnant women. It is usually positive within a week of a missed period. A morning specimen of urine is injected, in divided doses, into mice (Ascheim-Zondek) or rabbits (Friedman). A positive test is indicated by the resulting formation of blood spots, or of corpora lutea, in the ovaries.

SEXUAL PRECOCITY

Synonyms.—Pubertas Præcox ; Macrogenitosomia.

Definition.—The attainment of sexual maturity in childhood some years before the normal time of puberty.

Ætiology and Pathology.—Sexual precocity may be due to a variety of causes, which ultimately belong to one of three groups, primary gonadal ; or primary adrenal ; or primary pituitary or hypothalamic-pituitary. Thus the underlying lesion may be an adenocarcinoma of the testis, a granulosa cell tumour of the ovary, an adenoma or adenocarcinoma of the adrenal cortex, a pineal tumour (which probably acts by stimulating the hypothalamic-pituitary mechanism), encephalitis, internal hydrocephalus, or a third ventricle tumour. There is also an idiopathic familial type of sexual precocity. Whatever the mechanism, the result is a hypersecretion of androgenic or œstrogenic hormone.

Symptoms.—In boys, the sexual precocity is shown by enlargement of the penis and sometimes of the testicles, development of hair on the pubis and to some extent on the face, and often considerable strength. The latter, vividly described as the Hercules type, was thought to be characteristic of adrenal tumours, but may also occur with hypothalamic or third ventricle tumours. The boys will show obvious sexual behaviour, even running after and attacking adult women, masturbating against their legs, which they may clasp with great strength and may bite with anger if frustrated. Seminal emission is rare, and fertilisation not recorded. The precocity may begin in very early childhood.

With girls, there are clinically two main types. When the condition is due to ovarian hyperactivity, either primary or secondary to a hypothalamic-pituitary stimulus, it is manifested by qualitatively normal sexual development, pubic hair, well-formed breasts, menstruation, and even pregnancy, the last having been recorded as early as 6 years of age. With adrenal tumours, menstruation is usually absent, the clitoris is enlarged, the voice is deep, and hirsutism occurs on the face and body, as in virilism. These manifestations are due to the secretion of androgenic hormone by an adrenal tumour.

In both sexes, the sexual maturity is associated with premature dentition, and early union of the epiphyses. Rapid growth occurs, both with pituitary and adrenal tumours, suggesting that in the latter case the pituitary must also be involved (growth hormone). Although the instincts may be adult, the intellectual activity is usually infantile.

Diagnosis.—In girls, an enlarged clitoris and hirsutism suggest an

adrenal tumour, whereas homosexual precocity suggests an ovarian tumour. In both sexes, but especially in boys, the cause of the sexual precocity is often obscure. Radiograms of the adrenal area, after uroselectan or perirenal air insufflation, and abdominal laparotomy are justifiable. Pineal tumours are associated with ocular palsies, disturbance of vision, somnolence and increased intracranial pressure. The skull should always be radiographed.

Prognosis.—Idiopathic or familial sexual precocity may proceed to a normal adult state. Adrenal and testicular tumours are usually malignant, whereas ovarian tumours are generally not so. Intracranial lesions may be mechanically fatal. Removal of adrenal or gonadal tumours tends to produce a reversion to normal in the absence of metastases.

Treatment.—Surgical removal of the adrenal or gonadal tumour is indicated. In the former case, desoxycorticosterone is given for 1 week before and for 2 weeks after operation. Intracranial lesions offer technical difficulties. Unilateral orchidectomy is not helpful, and complete castration should not be lightly undertaken.

PRESCRIBING AND ADMINISTRATION OF HORMONE PREPARATIONS

The increasing number of commercial firms producing hormone preparations and the variety of trade names employed tend to create a state of chaos. In my opinion, the only solution is prescribing the hormone by its scientific name and, if so desired, writing the name of the manufacturing firm in brackets after it. It is to be noted that the esters of the hormones are employed to give a more prolonged action.

ŒSTRADIOL BENZOATE

This œstrogenic hormone is the one usually used, and it is prepared by the conversion of crystalline œstrone, obtained from pregnant mare's urine, into œstradiol benzoate by hydrogenation and esterification. It can be given by intramuscular injection, by mouth, by cutaneous inunction, or in the form of vaginal or rectal suppositories. By injection the dosage is about one-fourth of that required by the other routes. For injection, œstradiol benzoate is prepared in ampoules of 1 c.c. oily solution containing 1000, 10,000, 20,000 or 50,000 international units. One mg. of œstradiol benzoate is equivalent to 10,000 international units. Tablets are prepared in strengths of 1000, 3000 and 10,000 international units. Vaginal or rectal suppositories contain 1000 and 10,000 international units (*i.e.* 0·1 mg. and 1 mg. respectively). Ointment containing 0·5 mg., 1 mg. or 2 mg. per gram, is put up in tubes of 18 or 25 grams. Standardisation of œstrogenic hormones is now by weight. Biological assay is by the production of œstrus in ovariectomised rats and mice.

Œstradiol is a natural occurring hormone obtainable from ovarian follicular fluid, but other œstrogenic hormones, which do not occur naturally, can be synthesised. Of these, stilbœstrol is prepared in 1 c.c. ampoules of oily

solution, containing 1 or 5 mg., and in tablets of 0·1, 0·5, 1 and 5 mg. One mg. is equivalent to 10,000 international units. Stilbœstrol is cheaper than œstradiol and equally efficacious, but it has the disadvantage of producing nausea and vomiting, and even skin rashes, in a small proportion of patients. Hexœstrol, a similar preparation, used in comparable doses, is apparently less toxic. Stilbœstrol ointment is also available in concentration of 0·1 mg. per gram of lanoline base.

PROGESTERONE

This hormone can be obtained from the corpus luteum, but is now generally prepared by synthesis. One mg. of progesterone is equivalent to 1 international unit. It is usually given by intramuscular injection, and is prepared in 1 c.c. ampoules of oily solution containing 1, 2, 5 or 10 mg. A further synthesis produces a compound of progesterone active by mouth, but the dosage by this route is four times that by injection. It is called anhydrohydroxy-progesterone, or pregneninolone, and is prepared in 5 and 10 mg. tablets. Standardisation is now by weight. Biological assay is by the production of secretory endometrium in young rabbits.

TESTOSTERONE PROPIONATE

Testosterone can be obtained from the testes, but it is prepared commercially by synthesis from cholesterol and subsequent esterification to the propionate. It is available for intramuscular injection in ampoules of 1 c.c. of oily solution containing 5, 10 and 25 mg. (1 mg. is equivalent to 50 international units). It is also effective by subcutaneous inunction (four times the intramuscular dosage), and for this purpose is prepared in tubes of 25 grams of ointment containing 2 mg. per gram, or in more concentrated form in tubes of 2 grams of ointment containing 25 mg. per gram. Methyl testosterone in 5 mg. tablets has been employed experimentally by the oral route, but is not yet available commercially. The dosage is some four times that by injection. Standardisation is by weight. Biological assay is by measurement of the increase of comb growth in capons.

GONADOTROPHIC HORMONE

The problem of scientific prescribing offers some difficulty in the case of the gonadotrophins, since the essential hormones have not been isolated, crystallised or synthesised. Gonadotrophin A is obtained from pregnant mare's serum, and its preponderate action in lower animals is follicle ripening; Gonadotrophin B is obtained from human pregnancy urine, and its preponderate action is that of luteinising. Both are given by intramuscular injection and are prepared in ampoules containing powder to be dissolved in 1 c.c. solvent, with the exception of one preparation, antuitrin S, which is in liquid form. Standardisation is by measuring the increase in weight of the ovary of immature mice, or by the production of œstrus in immature rats.

Gonadotrophin A: Antostab (Boots), 100 units per c.c.; Gestyl (Organon), 400 units per c.c.; Gonadyl (Roussel), 40 units per c.c.; Prolan (Bayer), 100, 500 and 2000 units per c.c.; Serogan (B.D.H.), 200, and 1000 units per c.c.

Gonadotrophin B: Antuitrin S (Parke, Davis & Co.), 100 and 500 units per c.c.; Gonan (B.D.H.), 100 and 500 units per c.c.; Physostab (Boots), 100 units per c.c.; Pregnyl (Organon), 100, 500 and 1500 units per c.c.

ADRENAL CORTEX HORMONES

The essential hormone, desoxycorticosterone acetate, is prepared by synthesis from cholesterol, and is available for intramuscular injection in 1 c.c. ampules of oily solution containing 5 mg. One c.c. ampoules of benzyl alcohol, containing 20 mg. of desoxycorticosterone acetate, may be used for cutaneous inunction, but are not yet commercially available. Cortical extracts are also prescribed as solutions for intramuscular injection, and are labelled in rat units, dog units, or according to the weight of crude cortex. Generally speaking, they do not differ from one another in relative potency. Such preparations are Cortin (Organon), Eschatin (Parke, Davis & Co.), and Eucortone (Allen & Hanburys, Ltd.), usually prescribed in rubber-capped bottles of 10 c.c. They are standardised by their maintenance of adrenalectomised rats, or dogs, or by measuring the muscular contraction of the gastrocnemius muscle of adrenalectomised rats, before and after the injection of the cortical extract.

GROWTH HORMONE

This is prepared by Parke, Davis & Co., and called Antuitrin Growth. It is available in rubber-capped bottles of 10 c.c., each c.c. containing 10 rat units. Organon have a similar preparation (Crescormon) in powder and solvent ampoules, each containing 120 rat units. Growth hormone is standardised on hypophysectomised rats by measuring the increase in body weight and the increase in length of the tail vertebræ seen radiologically.

PROLACTIN

This lactogenic hormone is presented in 15 c.c. rubber-capped vials containing 60 Riddle units per c.c. (Physolactin-Glaxo); or 30 Riddle units per c.c. (Prolactin-Organon). It is standardised by the increase in weight of the crop gland of an injected pigeon.

S. L. Simpson.

SECTION IX

DISEASES OF THE DIGESTIVE SYSTEM

DISEASES OF THE MOUTH

ORAL SEPSIS[1]

Oral sepsis is the condition in which excessive bacterial activity occurs in the mouth. Apart from actual infection associated with the teeth and gums, it develops whenever insufficient attention is paid to the cleanliness of the mouth. Thus particles of food may stagnate between the teeth, under bridges, and in connection with badly fitted dental fillings, crowns and plates which are not removed and washed with sufficient frequency.

The mouth should be thoroughly examined in every patient, from whatever condition he may be suffering, but with special care in all digestive disorders and in those conditions which will be presently described as possible sequels of oral sepsis, even if the patient says he has never suffered from toothache and that he regularly visits his dentist. In patients who wear tooth-plates the mouth should be examined both before and after their removal. Each tooth and the gum surrounding it should be carefully inspected. The presence of tartar and red swollen gums indicates that some infection is present. In doubtful cases the patient should be sent to a dentist for an expert opinion, and if no obvious disease is found, radiographs should be taken, as they alone can show with certainty the existence of septic foci under apparently well-fitting crowns and fillings and at the roots of teeth which are otherwise perfectly healthy, and they make it possible to determine with great accuracy the extent of any periodontal infection.

Dental Hygiene

Dental sepsis does not occur if the teeth are always kept free from food between meals. The teeth should be thoroughly cleaned every morning and evening by brushing in one direction only—from the gums towards the teeth.

Normally the gums completely fill the spaces between the teeth, but when they begin to recede, as in pyorrhœa, the spaces are no longer filled and food collects between the teeth. As this food cannot be removed by a tooth-brush, the brushing must be followed at night by the use of a metal tooth-pick, bent at an angle so that it will pass readily between the molar teeth. Patients with inflamed gums or pyorrhœa should also massage the gums with the forefinger and thumb from the gum towards the teeth after

[1] I am indebted to Mr. A. L. Spencer-Payne for help in revising this section.

using the brush, and the dried gum margin should be painted with tincture of iodine applied on a small swab of wool held by curved dental tweezers.

Artificial teeth should be kept in antiseptic at night, and should be thoroughly scrubbed with a brush and soap and water, if possible after every meal.

Children should be given some food at each meal which requires thorough mastication. Soft food, which can be swallowed without chewing and with the production of little or no saliva, is likely to cause stagnation of sticky carbohydrate material between the teeth. Mouth-breathing should be corrected by direct treatment of nasal obstruction and by respiratory exercises.

At the end of every meal some fluid should be drunk, or some fresh fruit, the acid of which excites the flow of saliva, should be eaten in order to keep the teeth clean.

The dentist should be visited twice a year, even when there is no reason to suppose that anything is abnormal, so that tartar can be removed, early caries dealt with, and pyorrhœa alveolaris recognised and treated in its earliest stage.

(1) Pyorrhœa Alveolaris; Chronic Periodontitis

Ætiology and Pathology.—Stagnation of food mixed with pyogenic organisms between the teeth leads to inflammation of the edge of the gums —marginal gingivitis. The attachment of the muco-periosteum to the neck of the tooth is destroyed, and a pocket develops between the tooth and the gum. The margin of the alveolar process is then slowly eroded as a result of rarefying osteitis, until it may finally be replaced by granulation tissue. Stagnation of infective material in the pocket leads to gradual extension of the disease and aggravation of the gingivitis. Pus is produced, the condition at this stage being commonly known as pyorrhœa alveolaris.

Symptoms.—In marginal gingivitis the edge of the gum of one or more teeth is red and swollen and bleeds with abnormal ease when brushed, the first part to be affected being usually the interdental papillæ. When pyorrhœa alveolaris has developed, pockets are present round the teeth, and pus can generally be seen exuding from the edge of the gum; even when none is seen on first examining the mouth, beads of pus appear if the edges of the gum are pressed. In chronic cases the teeth are often loose. Reflex salivation occurs, and an excessive quantity of mucus is secreted by the small mucous glands of the mouth. This is a common cause of aërophagy. The accumulation of decomposing food, debris and pus in the pockets round the teeth produces an unpleasant taste in the mouth, most marked on waking in the morning, and is a common cause of foul breath. There is no pain, and the slight discomfort which may be present is generally insufficient to induce the patient to consult a dentist.

Treatment.—In early cases the disease can be arrested by sealing and treatment of the pockets with strong antiseptics. When the supporting bone has been destroyed to more than half the depth of the root, extraction is necessary. In intermediate cases the gum should be cut away in order to eradicate the pockets. This should be followed by correct brushing, and massage by the fingers of the outer and inner surfaces and by wooden toothpicks between the teeth.

(2) Dental Caries

Ætiology and Pathology.—Foods containing a relatively high content of vitamin D promote the calcification of teeth, whilst cereals, especially oatmeal, contain a substance which hinders calcification. When vitamin D is abundant in the diet its calcifying power is strong enough to counteract the effect of cereals and of a relative deficiency of calcium. Dental caries occurs when the diet is deficient in vitamin D, especially when this is associated with excess of cereals or deficiency in calcium. The organic acids produced by fermentation of carbohydrate foods is an additional factor.

Symptoms.—Carious teeth are tender, and their presence renders mastication painful. The patient therefore avoids using the affected teeth, and this favours the deposit of tartar and the stagnation of food. If many teeth are affected the food is bolted, so that indigestion is likely to occur owing to insufficient mastication, quite apart from possible infection of the alimentary canal caused by swallowing septic material from the mouth. The irritation produced by the decomposition of stagnant food around the teeth gives rise to marginal gingivitis and pyorrhœa alveolaris. Oral sepsis produced in this way is of much more importance than that caused by the caries itself, as the quantity of decomposing material and bacteria swallowed from dental cavities is comparatively small, and no local absorption of toxins or bacteria can occur so long as the pulp cavity is not reached. When the latter becomes infected, absorption of toxins is likely to lead to enlargement of the cervical glands, especially in children, and the chronic inflammation produced in this way is a common precursor of tuberculous infection of the glands, and probably also predisposes to lymphadenomatous changes. Inflammation of the pulp spreads to the periodontal membrane and may finally produce an alveolar abscess.

Dental caries is the most common cause of toothache, and pain is often referred to various situations more or less remote from the teeth.

Treatment.—" A relatively high vitamin D content of the food can do much to diminish the incidence of caries in children if the vitamin is given during the development of the teeth; a beneficial effect may be obtained if it is given at a fairly late stage of development; and even when it is given after the eruption of the teeth the onset and spread of caries is delayed." [1] The chief source of vitamin D is milk, and, when necessary, cod-liver oil or synthetic vitamin D (calciferol) should be given in addition.

Dental cavities produced by caries should be filled at the earliest possible moment, but if this cannot be efficiently done the teeth should be extracted, as tender teeth which prevent proper mastication are a much greater source of danger than the absence of teeth, even in very young children. Removal of all the milk-teeth in children may cause narrowing of the dental arch and consequent crowding of the permanent teeth, but this can be easily remedied by treatment, whereas the septic condition of the mouth caused by extensive caries may lead to permanent ill-results.

(3) Apical Infection

Ætiology.—Infection of the apex of the root of a tooth can occur only if the pulp is dead, except in rare cases of extensive caries.

[1] Medical Research Council, Special Report, No. 211, 1936.

Symptoms.—Apical infection may be acute or chronic. In the former an alveolar abscess forms; this gives rise to the usual symptoms and signs of inflammation. Chronic apical infection, on the other hand, frequently gives rise to no pain or discomfort, and no signs recognisable on ordinary examination. It can then be recognised only in a good radiograph.

Treatment.—In cases of only moderate severity the pulp canal should be opened and sterilised with ammoniacal silver nitrate followed by formalin, or by ionization with zinc chloride, and the root should be filled to its apex with an impervious material. In more advanced cases, and in all in which secondary symptoms are present, extraction should be performed without delay and the socket should be curetted.

Results of Oral Sepsis

The inflamed condition of the gums often leads to general stomatitis and sometimes to chronic pharyngitis and tonsillitis. Infection of teeth in the upper jaw may spread directly to the antrum and lead to sinusitis. Inhalation of septic material from the mouth may lead to infection of the bronchi and lungs, the danger of pulmonary complications after general anæsthesia being greatly increased if the mouth is in a septic condition. Chronic bronchitis and bronchiectasis often improve rapidly when oral sepsis is overcome.

Most of the pus which is constantly forming round the teeth in pyorrhœa alveolaris is swallowed; the amount is often considerable, as the ulcerated area round each tooth may be as great as half a square inch. During the day the infected pus is so diluted by what is eaten and drunk that it cannot do much damage, most of the bacteria being destroyed by the hydrochloric acid in the stomach. During the night, however, when no hydrochloric acid is secreted and nothing is eaten or drunk, the pus and organisms which are constantly swallowed with the saliva may infect the stomach and intestines. Pyorrhœa alveolaris is thus an important factor in the production of chronic gastritis, especially in individuals with hypochlorhydria and achlorhydria. In those with constitutional hyperchlorhydria it may help to prevent the healing of a chronic gastric or duodenal ulcer. The danger of infecting the small intestine and, through it, the colon, and of ascending infection of the gall-bladder and appendix is greatly increased in the absence of the normal bactericidal action of the gastric juice in achlorhydria.

The local reaction in pyorrhœa and in apical infection may be sufficient to prevent the passage of toxins and organisms into the circulation. In many cases, however, toxins are absorbed. Non-hæmolytic strep[illegible] found in the blood immediately after the extraction of teeth in 75 [illegible] cases if chronic gum infection is present, and less frequently with a[illegible] infection. The trauma caused by "rocking" a tooth during its removal increases the liability to a severe degree of bacteriæmia. The bacteriæmia generally lasts only ten minutes, but occasionally subacute streptococcal septicæmia follows, and, if the heart valves are already abnormal, subacute infective endocarditis may develop.

Apart from bacteriæmia the toxæmia caused by chronic dental infection may give rise to general ill-health, which may be accompanied by septic anæmia and slight chronic pyrexia. Predisposed individuals may develop rheumatoid arthritis, fibrositis, neuritis, and less frequently iridocyclitis.

Other forms of joint disease, such as gout and osteoarthritis, may be aggravated by the toxins resulting from oral sepsis. Various disorders of the skin, such as chronic eczema, urticaria, rosacea and erythema, may also occur, and angioneurotic œdema is generally secondary to dental sepsis. The causal connection between these conditions and dental sepsis is shown by their temporary aggravation after an overdose of autogenous vaccine and in some cases after extracting the teeth.

Treatment.—When dental extraction is required in patients with old valvular disease of the heart, great care should be taken to eliminate gross infection as completely as possible before the operation, and manipulation of the infected teeth during the extraction should be reduced to a minimum. In any case teeth should not be extracted until pockets have been thoroughly cleansed or sterilised by the electric cautery. With more local infection and in the presence of general disease the patient should be desensitised by giving two or three doses of an autogenous vaccine, the last about five days before the first extractions. If many teeth are infected, two or three should be extracted at intervals of about five days in order to reduce the risk of a severe reaction.

Although the masticatory power of artificial teeth is only about one-fifth of that of normal teeth, indigestion is unlikely to result if care is taken to avoid tough meat and hard food. Even in the absence of artificial teeth no disturbance of digestion follows if only soft food is eaten.

The removal of the teeth does not result in the complete eradication of the disease unless care is taken to remove at the same time the diseased parts of the supporting alveolus, as radiograms may still show small areas of rarefying osteitis, from which it is possible to obtain cultures of streptococci, which continue to give rise to general symptoms. Curetting the diseased bone after incision of the gum, followed by the use of an autogenous vaccine, is the most satisfactory treatment for such residual foci of infection.

STOMATITIS

Catarrhal Stomatitis

Ætiology.—Catarrhal stomatitis is common in ill-nourished children during dentition and in association with gastro-intestinal disturbances. In adults it may result from excessive consumption of alcohol or highly-seasoned food, or excessive smoking. It is sometimes present in the specific fevers, and may also be caused by septic teeth and a dirty or badly-fitting plate. It develops rapidly in very ill people whose mouths are not kept clean, especially if they sleep with the mouth open.

Symptoms.—The gums and lips are often affected alone; in other cases the whole mouth, including the tongue, is involved. The mucous membrane is red and dry, but excess of mucus may be secreted by the small buccal glands. The tongue is swollen and furred.

The mouth is uncomfortable, and occasionally actual pain is present, especially on mastication. The patient complains of a nasty taste, especially on waking, and fetor oris may be present. The general health is unaffected.

Treatment.—The teeth should be cleaned with special care, and the

tongue kept as free as possible from fur by scraping. A mouth-wash should be used after each meal, and glycerin of borax should then be applied to the inflamed parts.

Ulcerative Stomatitis

Ætiology.—Ulcerative stomatitis is not a specific disease, but is, like catarrhal stomatitis, produced by the action of various irritants. It can develop from neglected cases of catarrhal stomatitis, and is a prominent symptom of mercurial poisoning and scurvy. The following are special varieties of the condition:

(*a*) Recurrent Ulceration in Adults.

Single or multiple superficial ulcers may occur on the mucous membrane of the cheeks, lips, tongue and gums. They have a grey surface with a red, but not raised, border, and the intervening mucous membrane is generally healthy. In severe cases, however, the ulcer is deeper and its base bright red. Each ulcer generally lasts only a few days, but a patient may have one or more in his mouth for months, or even years, without an interval. They are often very painful, especially on chewing, and it may be impossible to take any acid food. Their ætiology is most obscure; the condition is aggravated by oral sepsis and ill-fitting plates, and some ulcers may begin as abrasions produced by the careless use of a tooth-brush, but it appears to depend primarily upon some obscure constitutional defect. It is not associated with any disturbance in digestion or with any special form of gastric secretion. The saliva is not acid and the ulcers do not appear to be infective in origin.

No treatment beyond scrupulous attention to oral hygiene and the application of silver nitrate to each ulcer as it appears is, as a rule, of any use. A severe recurrent case, associated with colitis, in a girl of seven, completely recovered after adding liver to the diet.

(*b*) Aphthous (or Vesicular) Stomatitis.

Ætiology.—Aphthous stomatitis occurs especially in children under three, either alone or associated with some febrile or digestive disorder.

Symptoms.—The aphthæ consist of small slightly raised vesicles, each surrounded by a red areola. Within 24 hours the vesicles rupture, leaving grey ulcers, 2 to 4 mm. in diameter, with bright red margins. The ulcers heal rapidly. They occur especially on the inner surface of the lips, the edges of the tongue and the inside of the cheek; in severe cases the pillars of the fauces may be affected.

The mouth feels sore, and the child is unwilling to take food. Salivation is frequently present.

Treatment.—The mouth must be carefully washed after meals with potassium chlorate solution (10 grs. to 1 fl. oz.). In severe cases the ulcers may be treated with silver nitrate.

(*c*) Follicular Stomatitis.

Ætiology.—Follicular stomatitis may occur at any age, but especially in nursing women.

Symptoms.—The mucous follicles of the lips and cheeks become inflamed

and swollen; the epithelium over them breaks down, and ulcers, 3 to 5 mm. in diameter, result. They may cause no trouble, but more commonly they give rise to a considerable amount of pain on taking food and to reflex salivation.

Treatment.—The ulcers heal rapidly after being touched with silver nitrate.

(*d*) Mercurial Stomatitis.

Ætiology.—Stomatitis may occur when large doses of mercury are taken, especially in individuals already suffering from oral sepsis. Some people are especially susceptible to mercurial poisoning and develop stomatitis after taking a comparatively small dose.

Symptoms.—The gums become sore, red, swollen and finally ulcerated; mastication is painful. Salivation occurs, and the salivary glands may be enlarged, tender and painful. The tongue is swollen, and the neighbouring lymphatic glands are often enlarged. The breath is foul, and the patient complains of a metallic taste. Formerly, when mercury was given for syphilis more frequently and with less care than at present, the teeth often became loose and the pharynx affected, but these complications are now rare.

Treatment.—The administration of mercury should at once be discontinued. The bowels should be wel lopened by giving salts in order to facilitate the elimination of the mercury present in the body.

(*e*) Ulcero-Membranous Stomatitis.

Ætiology and Pathology.—Severe ulcero-membranous stomatitis is a contagious disease, which occurred in epidemic form among the troops in England and France during the War of 1914–1918, and it is by no means rare in civilians. It appears to be caused by infection with the same spirilla and fusiform bacilli which cause Vincent's angina.

Symptoms.—All parts of the mouth and pharynx may be involved, but the margins of the gums are specially liable to be affected. The stomatitis is similar to that caused by mercury, and the gums may be so swollen and bleed so readily that scurvy is simulated. The breath has a characteristic fetid odour, and the tender gums may make mastication painful.

The disease is sometimes acute, but more often runs a chronic course and is often followed by pyorrhœa alveolaris. It generally gives rise to but little constitutional disturbance.

Treatment.—The pockets and interdental spaces should be packed with a paste of zinc oxide and cloves on strands of cotton-wool, which is left for at least a week. After removal the teeth should be scaled and any suspicious areas treated by leaving liquor arsenicalis in contact for 15 minutes. Sodium perborate should be used as a tooth-powder and hydrogen peroxide as a mouth-wash. Treatment must be maintained for at least a fortnight after all signs of stomatitis have disappeared.

(*f*) Gangrenous Stomatitis.

Synonyms.—Cancrum oris; Noma.

Ætiology.—This rare disease occurs in children, especially girls between the ages of two and five, who live under very insanitary conditions. It

generally develops during convalescence from an acute fever, especially measles, and less frequently scarlet and typhoid fever. It also forms part of the clinical picture of agranulocytosis (p. 800).

Symptoms.—A sloughing ulcer develops in the inside of the cheek or on the gums; it rapidly spreads and leads to brawny induration of the skin of the cheek. Occasionally it heals spontaneously, but more frequently it perforates the cheek or spreads to the tongue, chin, jawbone or eyelid and eye.

Cancrum oris is accompanied by severe constitutional symptoms, the patient being prostrated with a high temperature and rapid pulse; diarrhœa or broncho-pneumonia frequently follows, and death generally occurs between seven and ten days on the onset.

Treatment.—The only adequate treatment for cancrum oris in children is to destroy the diseased part as completely as possible with the cautery. For the treatment of agranulocytosis *vide* p. 801.

Thrush

Ætiology.—Thrush is most common in weak, emaciated infants with gastro-intestinal symptoms, who have been fed with an unsuitable diet, and whose mouths have not been kept clean. Acid fermentation of food remnants leads to catarrhal stomatitis, and this is likely to be followed by thrush. Thrush occurs in epidemic form in badly-managed institutions, being spread by dirty feeding-bottles. The disease may also occur in enfeebled adults in the late stages of tuberculosis, cancer and diabetes, and in severe febrile infections.

Pathology.—Thrush is caused by infection with *Oidium albicans*—a fungus, the filaments of which form a dense felt-work in the superficial epithelial layer of the mucous membrane.

Symptoms.—Thrush generally appears first on the tongue, and then on the cheeks, lips, hard palate, tonsils and pharynx. In rare cases the entire buccal mucous membrane is covered, and the infection may even spread to the vocal cords, œsophagus and stomach. It begins as slightly raised, pearl-white spots, which gradually grow and then coalesce. The white material can be readily detached, leaving either intact mucous membrane, or, in more severe cases, a bleeding and ulcerated surface.

Diagnosis.—Adherent milk curds may superficially simulate thrush. In aphthous stomatitis the white patches are at first vesicles and then definite ulcers, and salivation is present in contrast to the dry mouth in thrush. A definite diagnosis can be made only with the aid of the microscope.

Treatment.—Thrush should be prevented by keeping the mouth clean and babies' bottles sterilised. It is important to improve the patient's general health as well as to give local treatment. The mouth should be washed with sodium sulphite solution (60 grs. to 1 fl. oz.), after which the fungus can be easily scraped off.

Arthur F. Hurst.

DISEASES OF THE SALIVARY GLANDS

PTYALISM

Ætiology.—The flow of saliva is increased by reflexes originating in the mouth and also in more distant situations. Thus all pathological conditions in the mouth and its neighbourhood, such as stomatitis, epithelioma of the tongue and carious teeth, especially if associated with pain, are accompanied by salivation. Trigeminal neuralgia, whatever its cause, is frequently associated with a reflex flow of saliva. Mechanical irritation of the œsophagus caused by the passage of a tube into the stomach or by the impaction of a foreign body causes salivation, which is a common symptom in achalasia of the cardia and in simple and malignant ulceration of the œsophagus. Reflex salivation is the cause of waterbrash associated with the hyperchlorhydria of duodenal ulcer.

The salivation which may occur during menstruation and in the early months of pregnancy is also probably reflex in origin. Salivation is a common and sometimes very distressing symptom of paralysis agitans and post-encephalitic parkinsonism. Ptyalism may result from excessive smoking. It is also caused by the specific stimulating action of certain drugs, such as pilocarpine, and by drugs such as the iodides and mercury, which are partially excreted by the salivary glands.

Salivation due to any of the causes already described may be exaggerated or perpetuated by auto-suggestion (hysterical ptyalism).

Symptoms.—Every time saliva is swallowed some air passes with it into the stomach, which may therefore become distended with swallowed air. In neurotic individuals with ptyalism a spitting or swallowing tic may develop; the latter is always accompanied by aërophagy and the patient consequently complains of severe flatulence (p. 574). Excessive salivation may also cause waterbrash (p. 572).

Treatment.—In order to cure ptyalism the primary cause must be discovered and removed. As purely symptomatic treatment, belladonna should be given: 5 minims of the tincture, taken three times a day, half an hour before meals, is sufficient in the majority of cases, but occasionally much larger doses are required. The drug has the additional advantage of diminishing the secretion of gastric juice when gastric hypersecretion is the primary cause. Hysterical ptyalism can be cured by psychotherapy.

XEROSTOMIA

Ætiology.—The dry mouth, which is constantly present in fevers, is due mainly to deficiency in the psychical, chemical and mechanical stimuli to salivary secretion. The associated toxæmia probably also exerts some direct inhibitory action on the gland-cells. Depressing emotions and the loss or perversion of taste, which may occur when the tongue is furred, result in diminution in the psychical secretion. The paralysis of the secretory nerve-endings produced by belladonna, stramonium and their alkaloids

sets the limit to the dose of these drugs which can be administered. The secretion of saliva is also diminished when excessive quantities of fluid are lost by other channels, as in severe diarrhœa. Diseases of the salivary glands themselves, such as mumps, result in diminished secretion. Severe xerostomia occasionally develops without any obvious cause. Xerostomia is also a common result of sleeping with the mouth open.

Symptoms.—Deficient secretion of saliva causes the mouth to become dry and septic, as particles of food remain between the teeth, where they undergo bacterial decomposition. The tongue is furred and there is often an unpleasant taste in the mouth. It is difficult to chew food sufficiently, and the appetite is impaired as a result of the condition of the mouth and the difficulty in tasting. The insufficiently chewed food is likely to irritate the stomach. In severe cases dysphagia occurs and speech becomes difficult. The loss of the digestion of starch by the ptyalin of the saliva is of no importance owing to the amylolytic activity of the pancreatic juice.

Treatment.—A diet should be chosen which stimulates the flow of saliva; acids are most active, then salt and bitters, whilst sweet substances have very little action. The food should be given in as appetising a form as possible and masticated very thoroughly. If the saliva is only slightly deficient, dry biscuits should be taken at each meal. The taste of a bitter mixture taken immediately before meals may directly stimulate the flow of saliva, and pilocarpine may be tried, but it is rarely of much use, as a dose sufficiently large to increase the flow of saliva generally produces unpleasant symptoms, such as excessive sweating. It is, however, valuable in the treatment of paralysis agitans and post-encephalitic parkinsonism, as it counteracts the xerostomia (and also the paralysis of the intrinsic eye muscles) often caused by hyoscine and stramonium, without diminishing their effect on the tremor of paralysis agitans and the rigidity following encephalitis. Great care should be taken to keep the teeth clean, and the mouth should be washed after each meal.

SPECIFIC PAROTITIS (MUMPS)—(see p. 163)

PAROTITIS

Ætiology.—Parotitis is almost always due to infection ascending Stenson's duct from the mouth. This is particularly apt to occur in the acute parotitis that not infrequently follows operations on the alimentary tract, when the mouth has become septic owing to dehydration, the absence of chewing and normal salivation. It may follow obstruction by a stone in Stenson's duct. Subacute parotitis commonly occurs without obvious cause in persons with healthy mouths. Infection presumably ascends in these cases from the mouth, but may occur by direct spread from the tonsils, through the lymphatics draining an infected middle ear, or possibly by blood stream infection. This subacute or recurrent type of infection is relatively common in children and occurs more frequently in women than in men. An ascending infection may be limited to Stenson's duct, not involving the gland itself, and therefore giving rise to a condition of sialodochitis.

Symptoms.—In acute parotitis following operation both glands are

generally affected, except in mild cases when the condition is often unilateral. The glands are enlarged and tender, the skin over them stretched and shiny. In severe cases suppuration takes place, the neighbouring lymphatic glands enlarge, the temperature is high and constitutional symptoms are present. The mouth is dry and difficult to keep clean; the tongue is covered with a thick, dry fur. The mouth of Stenson's duct is everted and forms a small, red nodule from which a bead of pus can sometimes be squeezed. In milder cases the inflammation gradually subsides; rarely the condition becomes chronic, the parotid glands remaining permanently enlarged and secreting no saliva.

In the subacute form swelling of one or both glands may occur on a single occasion or repeatedly at intervals of weeks or months, sometimes over a period of many years. The swelling usually lasts for several days, but may persist for months. Fluctuation in the size of the swelling takes place, an increase usually accompanying or following mastication. The inflamed gland is painful to touch and the overlying skin may be reddened and hot. Firm pressure over the gland often causes expulsion of pus or turbid saliva from the reddened orifice of Stenson's duct. In recurrent cases the saliva is clear and free from debris between attacks. X-ray examination of the ducts after injection of lipiodol frequently shows bead-like dilatation of the terminal acini. In severe cases there may be irregular dilatation of the main and branch ducts.

Microscopical examination of the parotid saliva shows degenerated leucocytes, epithelial cell debris, and organisms. Streptococci and pneumococci are most commonly found.

Treatment.—The mouth should be kept clean with the greatest care and the flow of saliva promoted by means of chewing gum. In the acute cases, if suppuration occurs, the gland must be incised. In subacute cases, firm massage over the partoid swelling from the ear towards the angle of the mouth, especially at meal times, assists drainage. Local application of heat relieves pain and congestion. In chronic cases, the injection of 1 per cent. mercurochrome into the duct has proved helpful. Deep X-rays are also of value in chronic cases, but should be employed with care in the case of children.

NON-INFECTIVE RECURRENT SWELLING OF THE PAROTID GLANDS [1]

Ætiology.—This condition may occur at all ages. Its pathogenesis is unknown, but the frequent association with conditions, such as asthma, hay-fever and eczema, in the patient himself and in his relatives has led to the suggestion that in some cases an allergic process may be responsible. This theory is supported by the presence of eosinophil cells in the parotid saliva of some cases.

Symptoms.—Eating may precipitate attacks, especially when the food is acid in character, and in some patients the parotid glands become swollen whenever they take food over a period of years. Exposure to cold sometimes has the same effect. The swellings are more often bilateral than unilateral. They develop rapidly and are present for a short time only, often subsiding within half an hour and seldom persisting for more than 24 hours. Single

[1] I am indebted to Dr. R. S. Bruce-Pearson for this article.

isolated attacks may occur, but owing to their brief duration and the absence of after-effects such cases are seldom seen, and cases presenting themselves for treatment are usually recurrent. Signs of inflammation are absent, the parotid saliva contains no pus, and the swellings are seldom painful.

In some patients it is impossible to obtain saliva by pressure during attacks. In others the saliva differs from normal parotid saliva, as it contains globules of jelly-like mucus which obstruct Stenson's duct and may be expressed from it, to be followed by a flow of 2 or 3 c.c. of clear saliva. It is in this type of case that eosinophil cells are sometimes observed both in the mucous plugs and the pent-up saliva; the saliva is always sterile, but secondary infection may occur.

Sialography often reveals no abnormality, but it may show changes resembling those seen in the infected cases. Gross fusiform dilatations of the main and branch ducts are found in long-standing cases of mucous obstruction. Infective parotitis, and a stone in Stenson's duct, a rare condition, must be excluded before a definite diagnosis is made.

Treatment.—Massage over the gland is of value, especially when mucous obstruction is present. In some cases injection of adrenaline subcutaneously leads to subsidence of the swelling.

UVEO-PAROTID SYNDROME (HEERFORDT'S DISEASE)[1]

Definition.—Heerfordt drew attention in 1909 to the association of enlargement of the parotid glands with uveitis and facial paralysis, sometimes with lesions of other cranial nerves and a slight intermittent pyrexia.

Pathology.—The uveo-parotid syndrome is probably a special expression of that form of reticulo-endotheliosis, known as sarcoidosis. Cases have been described in which the uveo-parotid syndrome has been found associated with the skin, pulmonary and bone lesions characteristic of sarcoid. The tuberculin skin reaction is frequently negative, but a number of cases have come to autopsy in which miliary tuberculosis has been the cause of death. Sections of the parotid gland and iris removed during life show granulation tissue of fibrosing type with epithelioid and giant cells but little or no tendency towards caseation. The appearance of the nodules which occur on the iris in about a third of the cases is said to be characteristic of tuberculosis if syphilis and leprosy are excluded. It seems certain that at least one group of these cases is definitely tuberculous.

Symptoms.—The essential features are swelling of the parotid glands and inflammation of the uveal tract. In about half the cases there is in addition facial paralysis on one or both sides. Swelling of the lachrymal, submaxillary or sublingual glands is sometimes present, lymph glands may be generally enlarged, and the spleen may be palpable. Peripheral neuritis with loss of vibration sense, paræsthesia, anæsthesia, weakness of the limbs, and absent knee and ankle jerks, and paralysis of the cranial nerves other than the seventh have been described. Some fever is frequently present.

The parotid swellings are almost invariably bilateral, though one side may precede the other. They are firm and painless, often nodular, and sometimes confined to one part of the gland. They do not vary in size with

[1] I am indebted to Dr. R. S. Bruce-Pearson for this article.

the secretion of saliva. The orifices of Stenson's ducts and the sialographic appearance of the ducts are normal. The parotid saliva is clear, but may be diminished, leading to dryness of the mouth. The uveal lesions most commonly take the form of iridocyclitis, but choroido-retinitis and optic neuritis may be present; vitreous hæmorrhages have been described, and glaucoma and cataract may develop. Skin lesions, including erythematous rashes, indurated erythematous patches on the extremities, and erythema nodosum occur in approximately 20 per cent. of cases; some of these lesions are almost certainly due to skin sarcoid.

Diagnosis.—In the presence of bilateral uveitis, with swelling of one or both parotid glands, the diagnosis is not difficult. In some cases, however, the uveitis or parotid swellings may precede one another by an interval of some weeks. In the latter case subacute parotitis can be excluded by the absence of tenderness over the gland and of pus cells in the parotid saliva. Cases in which there is swelling of the lachrymal glands fall into the group included in the Mikulicz syndrome. A radiograph of the thorax occasionally reveals evidence of tuberculosis, or the nodular deposits of sarcoid. The small bones of the hand may also show the radiological appearance (" shot holes ") of the latter.

Prognosis.—The parotid swelling, uveitis and nerve palsies usually undergo apparently spontaneous cure in the course of some months or even after a period of two years. Recurrences may occur, either of the original lesion, of sarcoid elsewhere in the body, or of frank tuberculous infection. The uveitis is often followed by the development of posterior synechiæ, and vitreous opacities giving rise to impairment of vision are not uncommon. The facial palsy almost invariably recovers completely. In a small proportion of cases death resulted from tuberculosis.

Treatment.—General treatment as for tuberculosis, and the usual treatment of uveitis should be adopted. Tuberculin injections are dangerous on account of the severe focal reactions that may follow. Deep X-ray treatment of the parotid glands has been employed successfully.

ARTHUR F. HURST.

DISEASES OF THE TONSILS

ACUTE TONSILLITIS

Tonsillitis has been classified as superficial, follicular or lacunar, and parenchymatous, according to the degree in which the various parts of the gland bear the brunt of the inflammation; the distinction, however, is not a definite one, as the entire organ is necessarily inflamed.

Ætiology.—The disease is rare in children below the age of 5 or 6, and after middle age; and it is commonest in spring and autumn. It is predisposed to by general ill-health, overwork and a polluted atmosphere; the escape of sewer-gas from defective drains is a probable cause, and the infection may be carried by water or milk. It occurs as a regular symptom of scarlet fever, measles and diphtheria. There is a very close connection between rheumatism and tonsillitis, and it was formerly believed that tonsillitis was of

rheumatic origin; but it is now generally recognised that both acute rheumatic fever and chronic rheumatic pains in joints and muscles are frequently caused by septic infection through the tonsils. Unhealthy conditions of the tonsils due to previous inflammation strongly predispose to further attacks by causing adhesions in the crypts or supratonsillar fossæ, and between the tonsils and the pillars and plicæ, thus promoting the retention of secretion; previous partial removal acts in the same way.

Symptoms.—The symptoms are those of a feverish attack, together with a sore throat; the former often appears before the latter, and only examination of the throat reveals the cause of the disturbance. The temperature may rise to 103° or 105° F., and there is a variable degree of malaise, backache, headache and pain in the limbs. The soreness of the throat radiates to the ear, and is increased by attempts to swallow; the voice becomes thick, the breath foul, and the submaxillary and upper cervical glands are tender and swollen.

The tonsils are swollen, and their purple-red colour extends to the pharynx, palate and uvula—the latter frequently being œdematous. The surface of the tonsils is usually spotted over with yellowish masses of secretion which have exuded from the crypts; sometimes this secretion becomes confluent on the tonsils and occasionally, though rarely, it spreads beyond their surface—it is soft and readily wiped away. The tongue is coated, and the fauces covered with tenacious mucus. There is usually constipation, and the urine is scanty and high-coloured, but not ordinarily albuminous. Albuminuria is, however, an occasional complication, as are pericarditis, endocarditis and suppurative otitis media.

Diagnosis.—The diagnosis from diphtheria is important, and sometimes difficult. The latter is more gradual and asthenic in onset, with less pain, less fever and a more rapid pulse, and the urine frequently contains albumin. The membrane of diphtheria is greyish-white rather than yellowish, and frequently spreads to the pillars and soft palate; whereas the exudation of tonsillitis rarely spreads, and never to any great extent, beyond the surface of the tonsils. The diphtheritic membrane is adherent and, when detached, leaves a raw bleeding surface, while that of tonsillitis is readily removed and more often discrete. In cases of doubt a bacteriological examination should always be made, and an injection of antitoxin should be given while waiting for the result.

Treatment.—The patient should be kept in bed in a warm well-ventilated room, an initial dose of calomel, 2 to 4 grains, should be administered and followed by a saline aperient. Externally, warmth is usually more comforting than cold, and a hot fomentation applied to the neck and covered by a large pad of cotton-wool gives some relief. Internally, especially if the fauces are clogged with tenacious mucus, a warm alkaline lotion, such as Dobell's solution (see p. 1086), may be used with advantage, either by means of a spray or a rubber ball-syringe; but, if the inflammation is so severe that the patient is unable to open the mouth without pain, the lotion should only be used as a mouth-wash; gargling is, of course, only possible in mild cases. Lozenges containing potassium chlorate, guaiacum or formalin may be employed. Of internal medication, sodium salicylate holds the favourite place in doses of 15 grains every 3 hours, and later three times a day; or aspirin, 10 grains, may be used instead; potassium chlorate in 15-grain doses, three or four times daily, appears to be helpful, especially in the

follicular variety; and guaiacum, in the form of mistura guaiaci, was at one time in high repute. The patient must be encouraged to absorb as much nourishment as his dysphagia permits, and he will usually find that soft semi-solids are easier to swallow than liquids; there is room for ingenuity and resource in the provision of a suitable diet, such as junket, baked custard, ice-cream, meat jellies and soups thickened with corn-flour or arrowroot. An iron and quinine mixture may be given when the acute symptoms have subsided.

PERITONSILLAR ABSCESS OR QUINSY

Ætiology.—This is an acute affection due to the formation of an abscess outside the tonsil caused by septic secretions in the supratonsillar fossa or in the depths of a crypt bursting through the thin capsule of the tonsil into the surrounding loose areolar tissue. This process is favoured by adhesions obstructing the mouth of the supratonsillar fossa or the crypts, and, therefore, previous tonsillitis and imperfect surgical removal are predisposing causes. The abscess is usually situated above and external to the tonsil, but in rare cases is behind it.

Symptoms.—The affection is unilateral; but sometimes the opposite side is attacked as the first recovers. It begins with a feeling of malaise, fever, often a rigor, and severe pain radiating from one side of the throat up to the ear and into the neck; the cervical glands are enlarged and tender, and the neck stiff. Dysphagia is intense, the tongue thickly coated, and the breath foul. The mouth cannot be opened widely, and a good light is required for examination, when the typical large deep-red swelling is to be seen bulging one side of the soft palate. Pus forms in 2 to 4 days and, if left alone, will eventually burst, usually through the soft palate; relief is then immediate, but occasionally the opening closes prematurely and the abscess refills.

Complications.—Although one of the most painful and distressing of acute diseases, complications are uncommon, and death is very rare; it has occurred from rupture of the abscess, and inspiration of the pus, during sleep. Severe hæmorrhage may take place after spontaneous or surgical evacuation of the abscess when, as the blood may come from the internal carotid or from a branch of the external carotid artery, ligature of the common carotid is called for. The swelling has been known to spread to the larynx, and to necessitate tracheotomy. Suppuration of the cervical glands is a rare complication, as are pneumonia, septicæmia and pyæmia.

Treatment.—The general treatment is the same as that of severe acute tonsillitis, and the pain sometimes calls for an occasional injection of morphine. Pus is probably present as soon as the swelling has assumed a well-defined rounded form, still more so if there is a boggy area in the centre. The abscess should be opened without delay, for this cuts short the attack and diminishes the risk of complications; but it does not always give immediate complete relief when there is marked cellulitis of the surrounding tissues. After the application of cocaine, a narrow sharp-pointed knife is introduced with the cutting edge upwards and the blade held in the sagittal plane; it is made to puncture the swelling at its most prominent part, and to enlarge the incision by cutting upwards as it is withdrawn. The knife should not be passed to a depth exceeding about $\frac{3}{4}$ inch; if pus is not struck, a sinus-forceps is intro-

duced into the wound and pushed backwards until the pus is found, when it is opened widely to assist the evacuation. After the disease has subsided, removal of the tonsil is advisable, in order to prevent recurrence.

CHRONIC TONSILLITIS

Chronic inflammation of the tonsils may, from the clinical point of view, be divided into two groups: Chronic Parenchymatous Tonsillitis or "enlarged tonsils," and Chronic Follicular Tonsillitis.

Chronic Parenchymatous Tonsillitis

Enlarged tonsils in children are nearly always associated with adenoids; but adenoids are often found in children whose tonsils are not enlarged.

Ætiology.—This is similar to that of adenoids. The condition occurs chiefly in children between the ages of 5 and 15; but it frequently persists into adult life, although normal healthy tonsils atrophy about puberty and hypertrophy seldom takes place *de novo* after that age. The affection may be the result of repeated colds or a sequela of scarlet fever, diphtheria, measles or whooping-cough.

Symptoms.—The symptoms are not easy to separate from those caused by the concomitant adenoids, but it is certain that chronic inflammation of the tonsils can affect the ears, and that gastro-intestinal disturbances and appendicitis are produced by the septic secretion squeezed out of the tonsils during deglutition. Recurrent attacks of acute tonsillitis are common; and the cervical glands are frequently enlarged, may break down and suppurate, or may become tuberculous.

The objective appearances are very various, and it is extremely difficult to estimate the healthiness of a tonsil by inspection. Slightly enlarged tonsils may be prominent and may readily meet on gagging, while big tonsils are often largely buried in the palate or hidden beneath the plica triangularis —in which case a bulging can be seen at the side of the soft palate corresponding to the site of the upper pole.

Treatment.—For children with slight degrees of tonsillar hypertrophy, palliative measures may be tried; an open-air, country life, preferably at the seaside, with cod-liver oil, malt, or iodide of iron, and a nasal lotion for the accompanying adenoids; paints are of doubtful utility, Mandl's solution (iodine, grs. 6, potassium iodide, grs. 12, peppermint oil, min. 3, glycerin, 1 fl. oz.) is perhaps the best.

The tonsils should be removed when there have been repeated attacks of tonsillitis, after a quinsy, with any affection of the middle ear, when there is chronic enlargement of the cervical glands, and when rheumatic fever or chorea has occurred. When chronic cervical adenitis is present, and is not due to some other obvious cause, such as pediculosis or dental caries, the tonsils should be removed whether they appear diseased or not; in these cases about one-third of the tonsils are tuberculous, and this latent tuberculosis cannot be recognised by inspection, many of these tonsils, indeed, being quite small.

The reader is referred to surgical works for details of the operation, but

it may be said here that, if a tonsil requires removal, it must be removed completely in its capsule, for the deeper portion of a diseased tonsil is quite as unhealthy as the superficial; trouble in the remaining portion is very common, and the previous operation only adds to the surgeon's difficulties. In cases where operation is inadmissible, the tonsils may in adults be treated by diathermy, or by application of a caustic, "London Paste," which consists of equal parts of caustic potash and unslaked lime made up into a stiff paste with absolute alcohol. A general anæsthetic is not required, but repeated treatments are necessary, which are not free from pain, and all the tonsillar tissue can only be extirpated by unusual perseverance.

Chronic Follicular Tonsillitis

In older subjects, when fibrosis has followed the hypertrophy, the stenosed crypts become filled with yellowish-white caseous masses. The patient complains of an offensive taste, foul breath, often of recurrent attacks of sore throat, and of gastric disturbances. Not infrequently various forms of chronic toxæmia, such as fibrositis or osteo-arthritis, are induced by absorption from these septic foci. In many cases the tonsils are quite small; they may look healthy, but pus can be squeezed out of the crypts on applying pressure at the anterior pillar by means of a flat instrument.

Treatment.—The treatment in the more marked cases is removal. There are, however, a good many patients who have only a few unhealthy crypts in the tonsils; these may often be cured by passing a fine galvano-cautery point down to the fundus, several applications being usually necessary. The patient may also be shown how to clean out the secretion with a cotton-wool mop on a fine wooden applicator, and to paint the inside of the crypt with Mandl's solution.

VINCENT'S ANGINA

Ætiology.—This affection is believed to be due to two organisms, the bacillus and spirillum of Vincent growing in symbiosis; these organisms may be found in many ulcerative conditions of the mouth and throat, but their constant presence in this affection points to their specific character. The invasion of the throat is frequently secondary to periodontal infection of the gums. It occurs especially in debilitated persons and under insanitary conditions and, though rather rare in civil life, was common during the War of 1914–1918 in some camps and barracks.

Symptoms.—The attack begins insidiously, with malaise, general pains and a temperature of 100° to 101° F. The pain in the throat is slight, but the glands on the affected side become enlarged and tender, and the breath is usually offensive. The affection is nearly always unilateral.

At first there is a patch of soft, yellowish detachable membrane on the affected tonsil which, in a day or two, comes partially away, exposing an ulcer with a well-defined margin. By the end of a week the membrane ceases to form, and the ulcer begins to heal. The ulceration may be quite deep in severe cases, but is ordinarily limited to the tonsil, and very seldom spreads to any distance from it.

Complications are very rare.

Diagnosis.—The disease is particularly interesting by reason of its liability to imitate diphtheria in its early stage, and syphilitic ulceration later. In both cases the discovery of numerous spirilla and fusiform bacilli in smear-preparations—they are difficult to cultivate—will help the physician to the correct diagnosis; but these organisms may also be found in tertiary ulceration, and the Wassermann reaction is occasionally positive in Vincent's angina. The subacute onset, the raised temperature and the tenderness of the glands aid the differentiation from syphilis; and from diphtheria the milder constitutional symptoms, the extremely localised lesion, the soft friable character of the membrane and the absence of the Klebs-Loeffler bacillus.

Prognosis.—Death hardly ever occurs.

Treatment.—Topical application of weak solution of iodine was recommended by Vincent. Liquor arsenicalis and vinum ipecacuanhæ in equal parts, or neoarsphenamine in the strength of 20 grains to the ounce, are effective; these should be firmly applied on a swab, with due regard to their poisonous nature. Intravenous administration of one of the arsphenamine group of drugs is a valuable measure in the more severe cases. Attention should be paid to the condition of the gums and teeth.

HAROLD S. BARWELL.

DISEASES OF THE PHARYNX

DIVERTICULA (see p. 550)

ACUTE CATARRHAL PHARYNGITIS

This is not a very well-defined affection, and is usually accompanied by acute rhinitis on the one hand, and by laryngitis on the other; the tonsils also often participate in the inflammation.

Ætiology.—The affection is generally due to catching cold; it is also caused by traumatism of any kind and by the irritation of hot fluids, corrosives or chemical vapours, and it forms a part of various acute infectious fevers, such as measles, German measles, scarlet fever, influenza and typhoid.

Symptoms.—The discomfort varies from a tickling sensation, or the feeling of a lump in the throat, to severe dysphagia. The voice is husky and thick, and the cervical glands tender and somewhat enlarged. There is slight fever and general malaise.

The pharynx is to a varying degree red and swollen, especially at the sides behind the posterior faucial pillars, where the swelling forms the so-called "lateral bands." The palate is swollen and relaxed, and the uvula elongated. The posterior wall is often covered by a film of tenacious mucus.

Treatment.—The patient should stay in a warm room and avoid the irritation of smoking, talking, alcohol or irritating foods. Calomel, 2 to 4 grains should be given, and followed by a saline aperient. Aspirin, or sodium salicylate, is helpful, and, as the naso-pharynx is involved, the nose should be syringed with a warm saline lotion which may also be applied to the pharynx as a spray.

ACUTE SEPTIC PHARYNGITIS

This term includes a series of severe infective inflammations, erysipelas of the throat, œdematous, phlegmonous and gangrenous pharyngitis and laryngitis, and angina Ludovici. Any classification must necessarily be a clinical one, based on the severity of the symptoms and their localisation, for they can be produced by a variety of micro-organisms, though they are usually caused by a streptococcus. These severe inflammations are fortunately uncommon, and most often, though by no means invariably, occur in debilitated or alcoholic persons.

Symptoms.—These vary greatly with the severity of the infection, which ranges from a mild inflammation to the most severe septic intoxication. They include malaise, sore throat, dysphagia, hoarseness and dyspnœa. The temperature in some cases rises to 105° or 106° F.; but in many of the worst cases it is hardly raised at all, and may be subnormal. Pleurisy, pneumonia and pericarditis may ensue, or death may result from asphyxia; but the worst cases die from general toxæmia and heart failure, even within 24 hours of the onset of the disease.

The objective appearances, also, are very variable. The pharynx and palate are of a deep purplish-red, and there may be sloughy patches or pseudo-membrane. The entire mucosa may be enormously swollen, and the œdema may involve the upper aperture of the larynx and produce asphyxia. The sublingual region is sometimes occupied by a peculiar brawny swelling, of a hardness like wood, which spreads downwards into the neck to a variable extent, and is known as "angina Ludovici."

Treatment.—The patient must be in bed and well nursed, and every care must be used to ensure that he takes as much nourishment as possible. Polyvalent anti-streptococcic serum is sometimes very successful, and should be given early in a large dose (40 to 50 c.c.). Hot fomentations to the neck and inhalations of steam are comforting. Œdema of the upper aperture of the larynx should be treated promptly by scarification; free incisions should be made with a curved bistoury guided by the finger, and tracheotomy under local anæsthesia must not be delayed, if dyspnœa be severe or not relieved by scarification. For angina Ludovici a deep incision should be made in the middle line, as all anatomical landmarks have disappeared, and an attempt should be made to find pus with the finger or a director. Sulphanilamide, or one of its congeners, is now indicated in this as in other forms of streptococcal infection.

RETRO-PHARYNGEAL ABSCESS

There are two forms—(1) Acute, and (2) chronic.

1. The acute form occurs in children up to the age of 3 or 4, but is far more frequently met with in the first 12 months. It is due to suppuration in the prevertebral glands, situated behind the posterior pharyngeal wall, which retrogress and disappear in later life. The abscess results from absorption of sepsis from the nares, naso-pharynx, or fauces, and is sometimes secondary to an infectious fever.

Though rare, the condition is an important one, for it may easily remain unrecognised in a young infant, and it is usually fatal if left unopened. The symptoms are fever and restlessness, a hoarse cry and croupy cough, with difficulty in swallowing and dyspnœa. Such symptoms should arouse a suspicion of retro-pharyngeal abscess, which may be seen on inspection as a rounded swelling of the posterior pharyngeal wall. The abscess is often very large, and must be freely opened in such a way as to avoid aspiration of the pus, without an anæsthetic, and with the child firmly held, either on the side with the face directed somewhat downwards, or on the back with the head hanging almost vertically. Recovery is rapid, and no after-treatment is required beyond attention to the enfeebled general health.

2. The chronic form, also, is found most frequently in children, but generally after the third year. It is of tuberculous origin, and is due either to tuberculosis of the prevertebral glands, or to caries of the cervical spine. The latter should be carefully excluded, for this abscess should on no account be opened through the mouth, as septic infection of the diseased bone will occur. The chronic glandular abscess, however, may be successfully opened and curetted by this route, though some surgeons prefer to treat them all by an incision behind the sterno-mastoid.

CHRONIC PHARYNGITIS

(Pharyngeal Hyperæsthesia)

The symptoms of discomfort in the throat in the conditions grouped as chronic pharyngitis bear little relationship to the intensity of the changes seen on examination. Many people, especially heavy smokers, complain of no discomfort, in spite of showing decided chronic inflammation; whereas others, in particular dyspeptic or anæmic women or those at the menopause, suffer great discomfort, with no apparent local abnormality. Indeed, in many cases the condition is better described as pharyngeal hyperæsthesia.

Ætiology.—The causes of chronic pharyngitis are most often found in nasal disease, which produces inflammation of the pharynx by causing mouth-breathing, and by the irritation of discharges; incorrect production of the voice is an important factor which is often in its turn dependent on nasal obstruction. Unhealthy conditions of the teeth or tonsils are further causes, as are the inhalation of irritating dust and vapours in various occupations, tobacco smoke and over-indulgence in alcohol. A long list of constitutional affections is active in the ætiology, such as gout, rheumatism, dyspepsia, anæmia, cardiac disease, cirrhosis of the liver, chronic bronchitis and pulmonary phthisis.

Symptoms.—The discomfort may take the form of aching, fullness, or feeling of a lump, a hair, or a pricking. The voice has a dead tone, and there is usually much hawking and frequent swallowing. The sufferer often becomes depressed, and fears that he has cancer of the throat. The unpleasant sensations are markedly lessened after a meal.

The mucosa of the pharynx and palate is thickened, and there is a loss of the finer modelling of the faucial pillars; the uvula is elongated, often slightly œdematous at its edges and tip, and fails to retract on phonation.

The posterior wall is covered by a film of mucus, which puckers up and becomes more obvious on touching it with a probe or swab. The wall of the pharynx is traversed by enlarged venules, and sometimes it is set with slightly raised pink lenticular nodules of lymphoid tissue, constituting a variety known as *granular pharyngitis*. In other cases two elongated masses of lymphoid tissue appear behind and parallel to the posterior pillars; these are the "lateral bands," and this form is called *lateral pharyngitis*. *Pharyngitis sicca* is a dry glazed condition usually dependent on rhinitis sicca or atrophic rhinitis, and occasionally the crust formation of the latter disease extends to the pharynx, causing a genuine *atrophic pharyngitis*.

Treatment.—The most important part of the treatment consists in the detection and alleviation of the cause, and should begin with a careful examination of the nasal passages. Cases of pharyngeal hyperæsthesia without obvious local changes are often harmed, rather than helped, by local treatment which directs attention to their trouble. Tobacco should be given up, and alcohol in concentrated forms, indeed the latter should be abandoned completely in plethoric patients and where the pharynx is congested; condiments and highly seasoned food should be avoided; this type of patient is benefited by a morning dose of sulphate of soda or magnesia, a teaspoonful in a glass of hot water while dressing, or by one of the natural mineral waters. When the pharynx is dry, or covered with tenacious mucus, an expectorant mixture gives relief, such as tinctura ipecacuanhæ, min. 12, vinum antimoniale, min. 5, potassium iodide, grs. 3, syrup of tolu, min. 60, water, 1 fl. oz., three times a day. The throat may be sprayed with a warm alkaline saline lotion, and the same may be, with greater advantage, syringed through the nostrils. Of local applications in the form of paints, iodine is the most generally useful, and may be applied daily by the patient as Mandl's solution; iodine, grs. 6, potassium iodide, grs. 12, peppermint oil, min. 3, glycerin, 1 fl. oz.; a 5 to 10 per cent. solution of resorcin in glycerin may be employed, or, if a more astringent effect is desired, iron-alum gr. 60, in glycerin, 1 fl. oz.; or the physician may himself apply, once or twice a week, nitrate of silver, grs. 10 to 30 to the ounce of water. In many cases, the galvano-cautery is of great value; it acts as a counter-irritant and astringent, and should be applied lightly and with caution. Prominent granulations may be destroyed and enlarged venules obliterated by this means, but deep eschars should not be produced, and only a few applications should be made at one sitting.

KERATOSIS PHARYNGIS

In this condition a number of sharply defined projecting white or yellow nodules occupy the surface of the tonsils; they also occur, though less profusely, scattered over the lingual and naso-pharyngeal tonsils and on any lymphoid granules in the pharynx. They occur at any age after childhood, and usually in persons in a poor state of health. The causation is unknown; the nodules consist of heaped-up epithelium and detritus containing numerous micro-organisms of the kind ordinarily present in the mouth. They sometimes disappear quickly, in other cases they remain for many months, or they may frequently recur. They produce no symptoms, or at most a slight discomfort, and are of interest chiefly because they are frequently mistaken

for the exudation of chronic follicular tonsillitis. Once seen they can, however, be recognised at a glance, for they are hard and adherent, discrete and prominent, and occur beyond the limits of the tonsils, on the pharynx and base of the tongue. They are usually discovered accidentally by the patient, who is naturally alarmed at their appearance. They are quite harmless, and local treatment is useless, for they are removed with difficulty and usually recur; it is wise to reassure the patient by telling him these facts and, if any treatment be required, to trust to attention to the general health, a holiday and change of air.

SYPHILIS

The *primary* chancre occurs on the fauces, occasionally on the pillars, palate or pharyngeal wall, but usually on the tonsil. In this situation the disease is apt to pass unrecognised, for the symptoms are usually slight and the lesion masked by the general inflammation of the tonsil; the typical induration is often absent, but there is always a characteristic bubo behind the angle of the jaw.

Secondary Syphilis

Secondary manifestations in the fauces are a part of the normal course of the general disease and are intensely contagious.

Symptoms.—The subjective disturbances are usually limited to dryness and discomfort. Objectively there are two types of lesion, erythema and mucous plaque. The former is a patchy, dusky red rash, with well-defined margins, somewhat symmetrical, and affecting especially the anterior pillars and soft palate. It is particularly associated with the early secondary symptoms; whereas the mucous patch may be present at the same time or may be found later, together with tertiary manifestations. The mucous plaque occurs on the soft palate, tonsils and pillars; in appearance it is a dusky, slightly-raised patch, with a sharply defined red margin, the surface is covered by a delicate milky-white layer of superficial necrosis resembling a "snail-track" or, if rather thicker, looking as if it had been touched with nitrate of silver.

Diagnosis.—The appearances just described are so characteristic that they are of great help in the diagnosis of the general affection; if their nature should be misinterpreted, other secondary symptoms nearly always co-exist to establish the correct diagnosis.

Treatment.—General treatment quickly cures these secondary lesions, though they may reappear during the first two or three years. Of local treatment, abstinence from tobacco and alcohol is important, as are the careful use of a tooth-brush after every meal and the employment of a mouth-wash, such as peroxide of hydrogen or potassium chlorate.

Tertiary Syphilis

Tertiary lesions usually occur about the third or fourth year after infection but may rarely be found within a few months or may make their appearance at any later time throughout the patient's life.

Symptoms.—Two principal forms may be described—(1) superficial ulcer, and (2) gumma.

1. The *superficial ulcer* may attack any part of the fauces, the posterior wall, tonsils, pillars or palate, a favourite site being the junction of the uvula with the edge of the soft palate. It has a flat base, with a smooth yellowish necrotic surface and a well-defined red margin, devoid of swelling or infiltration, and has a peculiar "serpiginous" contour as though marked out by segments of a series of circles.

2. A *gumma* is a localised infiltration which rapidly breaks down and exposes a deeply excavated circular ulcer covered with a thick yellow slough. One favourite site is on the posterior pharyngeal wall above the level of the palate, and another on the upper surface of the soft palate; in the latter situation nothing is seen from the mouth except a general dusky swelling of the palate until perforation suddenly occurs and irremediable damage has been done. After severe gummatous ulceration the resulting cicatricial contraction may bind the palate to the pharyngeal wall and partly or completely shut off the naso-pharynx from the mouth.

Of subjective symptoms, dysphagia may be very severe; nasal obstruction is present when the naso-pharynx is occluded by swelling or scarring; the voice is altered to a dead tone when there is nasal obstruction, or to the characters of a cleft-palate articulation if a perforation of the palate has occurred.

Diagnosis.—From an ulcerating malignant growth the diagnosis may be a matter of difficulty, especially as in syphilis the dysphagia may produce marked cachexia and loss of weight. The gummatous ulcer is excavated, covered by a dirty yellow adherent slough, its margin only moderately thickened, often overhanging, and surrounded by an area of deeply congested mucous membrane; the base of an epitheliomatous ulcer presents a nodular "cauliflower" aspect, and its edge is thick and everted; palpation with the finger is of great value, for the peculiar hardness of an epithelioma is highly characteristic. The superficial tertiary ulcer is usually easily distinguished from lupus, the ulcerations of which are surrounded by and dotted over with the characteristic granules, and the lesions of which occur on a pale mucous membrane, while manifestations of lupus are to be found elsewhere. Tuberculous ulceration of the fauces is superficial, but is more intensely painful than the superficial syphilitic ulcer, and is a terminal event in advanced pulmonary tuberculosis. Vincent's angina may closely resemble syphilitic ulceration of the tonsil, but is distinguishable by its more acute onset, raised temperature and tender glands. Actinomycosis, when it attacks the region of the tonsil, closely resembles an ulcerating gumma, especially as it improves under administration of iodides; the detection of the characteristic yellow granules will lead to their microscopical examination and recognition.

Treatment.—The most energetic general treatment may be called for to prevent perforation of the palate or severe cicatricial deformity. Local treatment consists chiefly in the use of antiseptic mouth-washes and gargles. Orthocaine (orthoform) by insufflation is helpful when there is dysphagia. The daily application of 3 grains of calomel, sublimed by a spirit-lamp and insufflated from a glass tube, is to be recommended in severe cases of ulceration.

LUPUS AND TUBERCULOSIS

Lupus occurs most frequently in young women. It usually shows evidence of having spread from the nasal passages, and attacks first the uvula and soft palate, whence it spreads to the faucial pillars. It appears as a patch made up of minute reddish nodules, each containing the typical "apple-jelly" centre; the surrounding mucosa shows no sign of inflammation. A progressive superficial ulceration gradually occurs, and may cause destruction of the uvula and part of the soft palate, while elsewhere scarring becomes evident and may finally result in considerable deformity. The subjective symptoms are limited to a feeling of stiffness and discomfort. The diagnosis is generally easy from the characteristic appearance, the chronicity, and the presence of lupus in the nares and on the skin. Syphilis is more rapid and does not spare the bony palate, which is never attacked by lupus. Lupus in the pharynx is far more amenable to treatment than in the nose, and may be expected to improve under the general anti-tuberculous régime of good food and open air; arsenic in full doses is very valuable, beginning with 5 minims of liquor arsenicalis three times a day, and increasing the dose gradually to 15 minims. Tuberculin has proved disappointing. Of local measures multiple puncture with a fine galvanocautery point is most useful, and massive patches of infiltration may be curetted.

Apart from the latent tuberculosis of the tonsils associated with cervical adenitis, which has been referred to under chronic tonsillitis, tuberculous disease of the pharynx is a rare affection; it occurs as a late and terminal complication of advanced consumption. The onset is acute; the affected parts, especially the soft palate and faucial pillars, are covered with numerous tiny grey tubercles on a bright red mucosa which soon break down to form multiple superficial ulcers with a flat greyish-yellow base. Pain is intense and swallowing becomes well-nigh impossible; treatment must be directed to alleviating the distress with insufflations of orthocaine, lozenges of cocaine or morphine, hypodermic injections of morphine or diamorphine, and saline and nutrient enemata.

INNOCENT TUMOURS

Papillomata are fairly common on the uvula, soft palate and faucial pillars and tonsils. They are small pedunculated warty growths and are easily removed. A flat sessile papilloma in this region must be regarded with suspicion as a possible early epithelioma and should be promptly excised by an elliptical incision around the site of origin.

Angiomata occur in the soft palate. Removal by the knife is a formidable matter and must be performed by incisions wide of the tumour. Diathermy excision, electrolysis, or cautery or diathermy puncture are preferable methods of treatment.

Dermoid cysts, teratomata and *mixed tumours*, resembling those found in the parotid, are occasionally observed.

MALIGNANT TUMOURS

Epithelioma attacks the tonsils, soft palate or pharynx; the lower pharynx behind the cricoid plate is often affected in females and at a younger age than is usual in cancer. Sarcoma usually originates in the tonsil and the cervical glands are secondarily involved, though generally somewhat late in the disease. In the earlier stages, malignant tumours of the tonsil resemble simple hypertrophy and may easily escape attention; in many cases enlargement of the cervical glands is the first symptom, and in such the tonsil should always be remembered as a possible site of the primary disease; palpation with the finger is of great service in its detection, the firm hard feel of a tumour distinguishing it from simple enlargement. Very early malignant tumours of the tonsil and palate may be removed through the mouth, and tumours situated low down in the pharynx may be reached by the operation of lateral pharyngotomy. The cervical glands should be cleared out. The final results of surgical extirpation of cancer of the tonsil are very bad, and radiotherapy may now be said to offer a better prospect of cure. Of palliative measures, diathermy may be used to remove the mass of the tumour, check fungation, and relieve symptoms. Oral hygiene, including the removal of all unhealthy teeth, antiseptic sprays and insufflation of orthocaine and benzocaine (anæsthesine) for dysphagia, will do much to relieve the severity of the symptoms. Palliative tracheotomy or gastrostomy, if required, should not be too long deferred.

HAROLD S. BARWELL.

DISEASES OF THE ŒSOPHAGUS

DYSPHAGIA

Dysphagia, or difficulty in swallowing, is generally the first symptom in diseases of the œsophagus. Owing to the fixed position of the œsophagus localisation of abnormal sensations is very accurate, and a patient generally points to the exact level of obstruction. In some cases, however, reflex achalasia or spasm occurs at the pharyngo-œsophageal sphincter simultaneously, so that the patient experiences difficulty in initiating the act of swallowing as well as feeling the obstruction in the passage down the œsophagus caused by the primary disease.

The causes of dysphagia can best be considered according to whether the difficulty is experienced at the upper extremity, near the middle, or at the lower extremity of the œsophagus; the last is the most common.

(*a*) *Pharyngo-œsophageal dysphagia.*—This is most commonly a result of neuro-muscular inco-ordination associated with atrophy of the glosso-pharyngeal mucous membrane and with anæmia (Paterson's syndrome). A similar inco-ordination is the cause of hysterical dysphagia, and difficulty in the initiation of the act of swallowing may occur in progressive bulbar paralysis, myasthenia gravis, and in the paralysis of the soft palate caused by diphtheritic neuritis. In comparatively rare cases epithelioma may

develop in this situation, and still more rarely dysphagia at the upper end of the œsophagus is caused by a pouch.

(*b*) *Mid-œsophageal dysphagia.*—This is almost always caused by epithelioma. External pressure by an aneurysm or mediastinal tumour rarely causes dysphagia. This is the situation of congenital strictures and strictures following injury caused by the impaction of foreign bodies, and I have seen mid-œsophageal strictures caused by cicatrisation of an ulcer following broncho-pneumonia and by syphilis.

(*c*) *Lower œsophageal dysphagia.*—Dysphagia at the lower end of the œsophagus is most frequently caused by achalasia of the cardia and by epithelioma of the œsophagus. Next most frequent is the dysphagia caused by spasm secondary to peptic œsophagitis and œsophageal ulcer, and by carcinoma of the fundus of the stomach. Lastly, the dysphagia may be due to cicatricial stenosis secondary to peptic ulcer or to the phlegmonous œsophagitis resulting from the swallowing of boiling water or corrosive poisons.

Upper Dysphagia with Anæmia

(Paterson's (so-called Plummer-Vinson) Syndrome)

Pathology.—In the voluntary initiation of swallowing the food is thrown to the back of the pharynx. The sphincter formed by the lower division of the inferior constrictor muscle of the pharynx (the "crico-pharyngeus muscle") at the junction of the pharynx and œsophagus, which is normally closed, then opens and allows the bolus to enter the œsophagus, along which it is carried by active peristalsis. In this syndrome, which occurs almost exclusively in middle-aged women, there is inco-ordination of the muscles concerned, and the sphincter fails to relax (achalasia) and may even contract spasmodically. As it is always associated with atrophic inflammation of the mucous membrane of the tongue, which spreads to the upper end of the œsophagus, it seems reasonable to suppose that the inflammation involves the myenteric (Auerbach's) plexus in the region of the sphincter, exactly analogous to what occurs in achalasia of the cardia. Both the atrophy of the mucous membrane and the anæmia are probably nutritional in origin, as most of the women affected have for long periods been living on an insufficient diet.

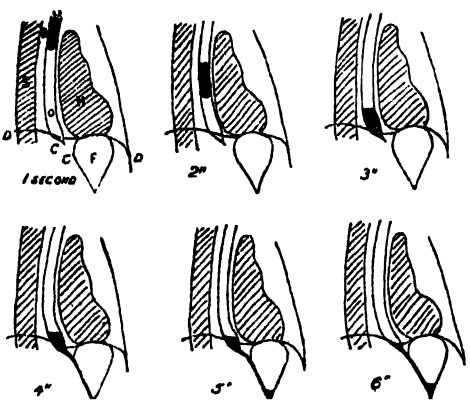

Fig. 14.—Diagrams of normal swallowing as seen with the X-rays in successive seconds. OO, œsophagus; B, bolus of food; CC, cardiac sphincter; DD, diaphragm; S, spine; H, heart; F, gas-containing fundus of stomach.

Symptoms.—The patient, who is generally an edentulous woman who has been in poor health for a long period owing to the presence of simple microcytic anæmia (*vide* p. 775), gradually finds difficulty in initiating the

act of swallowing, especially of solids. Sometimes, however, the dysphagia begins quite suddenly, and it may occur intermittently. It is frequently so slight that its presence is discovered only on cross-questioning a patient suffering from the other symptoms of the syndrome. The dysphagia is associated with atrophic inflammation of the mucous membrane of the tongue, which extends back to the entrance to the œsophagus. An atrophic condition also involves the lips, which are thin and inelastic with cracks at the angles of the mouth. Achlorhydria is frequently, but not always, present, and the spleen is enlarged in about 20 per cent. of cases. The nails are often thin, brittle and spoon-shaped (*koilonychia*).

The X-rays reveal no abnormality, and the œsophagoscope shows nothing more than an atrophic inelastic condition of the mucous membrane in the neighbourhood of the pharyngo-œsophageal sphincter.

The atrophic glosso-pharyngitis predisposes to epithelioma. About 50 per cent. of women with cancer of the mouth and a still larger proportion of those with cancer of the hypopharynx and upper end of the œsophagus give a history suggestive of the syndrome. The fact that the latter is almost confined to women probably explains why 80 per cent. of cases of cancer of of the upper end of the œsophagus occur in women, whereas at least 80 per cent. of cases of cancer of the middle and lower end occur in men.

Treatment.—A mercury bougie should be introduced into the œsophagus and passed from time to time until the dysphagia disappears. The anæmia responds to treatment with large doses of iron ; liver is without effect, except in the rare cases in which it is Addisonian. The atrophic condition of the mucous membrane also responds to iron therapy even if there is no anæmia.

Achalasia of the Cardia (so-called Cardiospasm)

Ætiology.—Achalasia of the cardia may begin at any age, but most commonly in adults, and males and females are equally affected.

Pathology.—The hypertrophy of the muscular coat of the œsophagus, which is always present in this condition, indicates that violent efforts must have been made to overcome some obstruction. As no organic obstruction is ever found after death it was at first thought that the spasm of the cardiac sphincter was present and the condition was called *cardiospasm*. As the symptoms may be present without intermission for many years before death, a considerable degree of hypertrophy of the cardiac sphincter would result from the long-continued spasm. In very few autopsies, however, has there been any hypertrophy, and in several cases in which the cardiac sphincter,

Fig. 15. - Drawings from a case of dilated œsophagus secondary to achalasia of the cardiac sphincter. (*a*) Dilated œsophagus filled with a 7-inch column of opaque food; sphincter closed. (*b*) Opaque food passing into stomach through sphincter which has opened after additional food has raised column in œsophagus above 7-inch height. (*c*) Return to condition of (*a*) after excess of food over the 7-inch column has entered stomach.

which is normally about one inch long and corresponds with the whole of the abdominal œsophagus, was exposed by operation, the muscle was found to be unusually thin. I believe that the obstruction is caused not by spasm but by achalasia (α, not; χαλάω, I relax), or absence of the normal relaxation of the cardiac sphincter, which should occur when each peristaltic wave reaches it (Figs. 14 and 15). Food stagnates in the œsophagus, which dilates as more and more collects in it; the distension of the œsophagus acts as a powerful stimulus to peristalsis, which is excessively violent and continues at intervals throughout the day. This is the cause of the hypertrophy.

Further evidence that the condition is due to achalasia and not to spasm is afforded by the fact that, although strong peristaltic waves are unable to overcome the obstruction, the weight of an indiarubber tube filled with mercury is sufficient to cause it to drop through the cardia into the stomach, the actual passage through the cardia being often inappreciable to the hand which holds the mercury bougie, which can be withdrawn with equal ease; it is not gripped, as the finger is gripped when it enters or is withdrawn from a spasmodically contracted anal sphincter.

The achalasia is a result of degenerative changes in the myenteric (Auerbach's) plexus between the circular and longitudinal muscular coats of the lower end of the œsophagus (Rake). The vagi themselves are unaffected. The degeneration is a sequel of inflammation, which spreads from the mucous membrane from a primary œsophagitis, or results from blood-borne infection or toxæmia and possibly from vitamin-deficiency.

The dilated œsophagus may be able to hold as much as two pints, and its circumference may exceed 6 inches.

Symptoms.—Achalasia of the cardia generally develops gradually, a slight attack, lasting for a day or two, being followed by a period of freedom for a few days or even several weeks or months. Attacks then occur at gradually shorter intervals, until finally the condition becomes permanent. The patient feels as if the food "sticks." He often recognises that the obstruction is beneath the lower end of the sternum, but sometimes the sensation is felt in the upper part or middle of the chest. Sometimes actual pain is produced. Salivation occurs in every case.

As a rule the patient voluntarily relieves his discomfort within a few minutes of finishing a meal by bringing up the greater part of what he has eaten mixed with saliva. He realises that this comes from his chest and not his abdomen, and, unlike true vomiting, it is not associated with nausea.

The weight of the column of food in the dilated œsophagus after a meal is sufficient to force a small proportion of the fluid present through the cardia as a very narrow stream; but as soon as the height of the column falls below a certain point, generally about 7 inches, or the individual lies down, the pressure becomes insufficient and the flow ceases (Fig. 15). Consequently, stagnating food mixed with mucus is always present in the œsophagus, and a considerable quantity can be removed from it even after a fast of 24 hours. No regurgitation occurs on lying down as the pharyngo-œsophageal sphincter is always, as in normal people, closed except during the act of swallowing.

The œsophagoscope shows that the entry to the cardiac sphincter, which is generally at the level of the diaphragm but may be within the thorax or within the abdomen, is completely closed. The mucous membrane may be

normal, but it is often red and inflamed, especially in the lowest part of the œsophagus, and there may be superficial erosions, which are secondary to the stasis.

The general health at first remains good in spite of the fact that weight is rapidly lost. After a certain amount of weight is lost, a condition of equilibrium develops; though extremely small quantities of food reach the stomach, the patient loses no more weight, and though he is less strong than formerly, he may continue to live in this condition for many years and attain old age.

Diagnosis.—The patient's description of his symptoms is generally so characteristic that a diagnosis of œsophageal obstruction can be made with a considerable degree of probability. This is confirmed by means of an X-ray examination, which must in the early intermittent stage be made during an attack, when the situation of the obstruction at the cardiac sphincter is at once apparent. It is next necessary to ascertain whether this is due to achalasia or to cancer, or to spasm associated with œsophagitis or a simple œsophageal ulcer, which may also give rise to a fibrous stricture. The intermittent character of the early attacks, the absence of serious constitutional symptoms in spite of rapid loss of weight, the comparatively early age at onset with many patients, and, in cases in which an early diagnosis has not been made, the long duration of the illness and enormous dilatation of the œsophagus point to achalasia rather than to growth. Occult blood is present in the stools in cancer, but never in achalasia of the cardia. In achalasia the shadow of the dilated œsophagus narrows abruptly and ends at the entry into the sphincter, either on a level with the diaphragm or a short distance above or below it. As each additional quantity of food is swallowed, a narrow and uniform channel is seen for a moment to join the œsophagus with the stomach before the sphincter closes again. In simple ulcer of the lower end of the œsophagus the sphincter remains open, but a narrowing is seen just above as a result of spasm with or without cicatricial contraction, and the round crater of the ulcer may be recognisable. In the cicatricial obstruction which follows caustic poisoning the obstruction extends for some inches upwards instead of being confined to the sphincter. In carcinoma the lumen of the cardiac sphincter is replaced by an irregular channel which extends a varying distance up into the œsophagus, the unaffected part of which is rarely as dilated as in achalasia. Further evidence pointing to achalasia is the ease with which a mercury tube passes through the cardia in contrast with the complete obstruction offered to its passage by a growth.

Prognosis.—If the condition is recognised at the onset of symptoms, a permanent cure often results from treatment, but if treatment is instituted only after the obstruction has become continuous and the œsophagus greatly dilated, cure as distinct from mere relief of symptoms is less likely to be obtained. In the absence of treatment death has occurred at an early stage in very acute cases; but more often the patient survives for a considerable period, even for 40 years. In rare cases a diverticulum may form in the lower end of the dilated œsophagus or cancerous degeneration of a wart developing on the chronically inflamed mucous membrane may occur.

Treatment.—The simplest and most effective treatment is by means of a series of mercury bougies, the smallest of which is 24- and the largest 34-gauge. They are made of rubber tubes closed at the top and with a

rounded lower end, and are half-filled with mercury. The whole series can generally be passed at the first sitting, which should be done with the guidance of the X-rays. Afterwards only the largest bougie which the patient can himself pass should be used. It drops easily through the cardia and requires no pushing. It is kept in position for a quarter of an hour on each occasion at first, but later it can be withdrawn directly after it has entered the stomach. The patient feels relieved and realises that "the passage is clear" as soon as it is withdrawn. It should be passed immediately before meals; the food then enters the stomach without difficulty. In very early cases the tube may only need to be passed once. Generally, however, the tube has to be passed before each meal at first, then once a day, and gradually less often, till finally it is only used at rare intervals when the patient feels that some slight obstruction is returning. In chronic cases, which are always associated with secondary œsophagitis, the diet for the first 2 or 3 weeks of treatment should consist of nothing but a pint of milk taken three or four times a day immediately after the passage of the bougie; half a pint of water should be drunk 10 minutes later. In the very rare cases in which a mercury bougie cannot be passed owing to the kinking caused by great elongation in addition to dilatation of the œsophagus, the cardiac sphincter should be stretched by the fingers inserted through an opening made in the stomach after laparotomy.

DIVERTICULA OF THE PHARYNX AND ŒSOPHAGUS

Ætiology and Pathology.—Diverticula may develop from the anterior wall of the middle third of the œsophagus by the traction resulting from adhesions between inflamed glands near the bifurcation of the trachea and the wall of the œsophagus; these "traction diverticula" are generally less than an inch in depth and rarely give rise to symptoms.

A diverticulum, which has given rise to no symptoms, is occasionally discovered at the lower end of the œsophagus during a routine X-ray examination. Its origin is generally obscure, but in one of the three cases I have seen it was associated with achalasia of the cardia.

Pressure diverticula are rare, but of considerable clinical importance. They occur only in adults, especially elderly edentulous men who habitually swallow lumps of unchewed food. They develop at the muscular gap on the posterior wall of the pharynx between the upper and lower divisions of the inferior constrictor of the pharynx at the level of the cricoid cartilage. They are really diverticula of the pharynx and not of the œsophagus, though they are generally described as œsophageal. The lower division of the inferior constrictor of the pharynx (the crico-pharnygeus muscle) forms a sphincter surrounding the entrance to the œsophagus. It is closed at rest, but opens during each act of deglutition the moment the food reaches it. When, as a result of a neuro-muscular inco-ordination, it fails to open (achalasia), the food is forced against the weak spot on the posterior wall of the pharynx immediately above the sphincter. A pouch of mucous membrane may thus be formed; it becomes progressively larger towards one side, generally the left, owing to the accumulation of food in it, until it may finally measure as much as 5 inches in depth and be large enough to contain over a

pint of fluid, in which case it may extend into the posterior mediastinum. Its wall is formed of mucous membrane and submucous tissue without any muscular covering.

Symptoms.—Diverticula of the pharynx sooner or later cause progressive dysphagia, but this may be preceded by irritation of the throat and increased secretion of mucus. The patient complains of obstruction in the neck when he swallows, and a small quantity of food is regurgitated at varying intervals after meals. As the sac increases in size, the symptoms become more marked owing to obstruction of the œsophagus by the distended diverticulum, which finally forms a prolongation of the pharynx, the œsophagus opening as a transverse slit in its anterior wall. Increasing quantities of food are brought up, mixed with a large amount of mucus, and food eaten several days before may be recognised. The patient becomes steadily more emaciated. Distension of the sac often causes pain, which is relieved when it is emptied. An irritable cough is often present, and dyspnœa may result from pressure on the trachea. A large diverticulum containing food may form a visible tumour in the neck, generally on the left side, which can be emptied by pressure, the food returning into the pharynx, but in most cases there is no palpable tumour.

The size, shape and exact position of the diverticulum can be recognised with the X-rays after a barium meal.

Treatment.—The only satisfactory treatment is excision. Whilst waiting for operation the patient should be fed through a catheter, which is introduced over a string swallowed when the sac is empty; if no fluids are taken for 5 or 6 hours the string always reaches the stomach.

ŒSOPHAGITIS

Two distinct forms of œsophagitis occur, both of which may be either acute or chronic. In one the irritants which cause it are either hæmatogenous or swallowed. In the other form, which, unlike the first, is often associated with ulceration, the essential factor is the presence of acid gastric juice in the œsophagus.

A. Simple Œsophagitis

(*a*) *Acute*

Ætiology.—Acute simple (non-acid) œsophagitis is a rare complication of various acute infections and toxæmias, such as scarlet fever. It may also complicate cancer of the œsophagus and spread from acute pharyngitis. In 5 per cent. of fatal cases of diphtheria the inflammation spreads from the fauces into the œsophagus, and in very rare cases the membrane extends as far as the cardia. The impaction of a foreign body in the œsophagus may cause local suppuration. Acute inflammation results from swallowing boiling water or corrosive poisons, taken by accident or in attempted suicide; owing to the obstruction to the passage of the œsophageal contents caused by the narrow cardiac sphincter the lower end is the part most affected, the upper extremity being next most seriously injured.

Symptoms.—In mild cases there may be no symptoms, but more or less dysphagia is generally present; in severe cases deglutition is so painful that the patient may be afraid to swallow his saliva or relieve his urgent thirst by drinking. There may also be constant pain beneath the sternum. Attempts to swallow often prove unsuccessful owing to reflex spasm and the food is immediately rejected. Mucus is expectorated, together with blood and pus in severe cases.

Treatment.—In severe cases nothing should be given by mouth, but saline solution must be injected into the rectum or intravenously. Morphine is required for the pain. When the pain begins to subside a tablespoonful of olive oil followed by 5 oz. of milk can be given in every 3 hours. Solid food should not be given until swallowing no longer causes pain. Complete obstruction necessitating gastrostomy is likely to occur in severe cases following corrosive poisoning.

(*b*) *Chronic*

Ætiology.—Chronic œsophagitis results from the constant swallowing of irritants, the most important of which are strong alcoholic drinks, and from septic conditions of the teeth and nasopharynx. It is also a common sequel of the stasis of food in the dilated œsophagus in achalasia of the cardia (p. 548).

Symptoms.—As the condition is frequently associated with chronic pharyngitis and gastritis, it is generally impossible to isolate the symptoms of one of these from the others. The morning vomiting of alcoholics is to a great extent caused by œsophageal catarrh.

Treatment.—The œsophagitis quickly disappears when the sources of irritation are removed. The patient should become teetotal, and all septic foci in the mouth and pharynx should be treated.

B. Acid Œsophagitis and Ulcer

(*a*) *Acute Acid Œsophagitis and Œsophageal Ulcer*

Ætiology and Pathology.—Acute peptic œsophagitis and œsophageal ulceration occur at all ages; the latter is one of the causes of fatal hæmatemesis and melæna in infants. It is always a sequel of severe vomiting in an enfeebled individual with low resistance. The acid gastric contents are retained in the œsophagus just above the closed cardiac sphincter, where their irritant action gives rise to inflammation, the lower end of the œsophagus being generally alone involved. In most cases the acute œsophagitis is associated with the presence of one or more acute ulcers just above the sphincter.

The majority of cases follow post-operative vomiting. Less frequently they result from the vomiting caused by pyloric obstruction secondary to a chronic gastric or duodenal ulcer. In one of my patients acute œsophagitis followed prolonged sea-sickness.

Symptoms.—The most common symptom of acute œsophageal ulcer is hæmatemesis. It may begin between 24 and 48 hours after an operation which has been followed by severe vomiting. Heartburn and occasionally a burning pain may be felt behind the lower end of the sternum, especially

on swallowing. The symptoms rarely persist for more than 10 days after an operation, but in other cases they may continue for long periods, though it is doubtful whether a chronic ulcer ever develops from this condition. Death may occur from hæmorrhage or from perforation of an acute ulcer into the pleural cavity, sometimes without any warning symptoms.

Treatment.—The patient should be kept in the erect position and given small feeds of citrated milk every 3 hours. Five minutes after each feed he should drink a few ounces of water.

(*b*) *Chronic Acid Œsophagitis and Œsophageal Ulcer*

Ætiology.—Simple chronic ulcer of the œsophagus was formerly regarded as little more than a pathological curiosity, but a recognition of its clinical features has in recent years shown that it is not uncommon. Since I became familiar with the clinical picture in 1929 I have seen about 20 cases in private patients in comparison with some 350 cases of duodenal and 70 of gastric ulcer. The incidence is greater among men than women; the majority of cases occur between the ages of 50 and 70.

Pathology.—Œsophageal ulcers have all the anatomical characteristics of chronic gastric and duodenal ulcers. In fatal cases heterotopic gastric mucous membrane has sometimes been found in the œsophagus; it probably secretes acid gastric juice, which collects in the lower end of the œsophagus immediately above the closed sphincter, and in course of time an erosion and finally a chronic ulcer develops. The condition is then analogous with the ulcers occasionally found in Meckel's diverticulum, which are always associated with the presence of ectopic gastric mucous membrane. In the majority of cases, however, the ulcer is associated with that form of diaphragmatic hernia of the stomach which is the result of congenital shortness of the œsophagus. For some unknown reason the cardiac sphincter is always relaxed in this condition, and consequently regurgitation of the acid contents of the stomach occurs on lying down and on increasing the intra-abdominal pressure by leaning forward.

Symptoms.—Discomfort or pain, often of a burning character and sometimes described as heartburn, occurs under the lower third of the sternum whilst eating solid food. The pain may also occur on leaning forward and shortly after lying down. It often radiates to the back and occasionally to the left shoulder or left side of the neck. At first the pain lasts for only a few minutes and is relieved by alkalis, but later it is prolonged and the patient may become frightened to eat. The food sometimes appears to stick at the lower end of the œsophagus before passing into the stomach. The spasm which causes the dysphagia sometimes leads to effortless regurgitation of sour material. The pain is relieved by alkalis and can generally be completely prevented by taking only fluid food. Progressive emaciation and anæmia are common in chronic cases. As with chronic gastric and duodenal ulcer, the symptoms at first occur for periods of varying duration with intervals of complete freedom.

Occult blood is always present in the stools. Hæmatemesis, which may be severe but is rarely fatal, is a common complication and may be the earliest symptom. Perforation into the mediastinum, pericardium or peritoneum is rare, but it is a more common cause of death than hæmorrhage. In very

chronic cases a fibrous stricture may develop and lead to more or less complete obstruction.

Hyperchlorhydria is generally present. The clinical picture may be confused by association with a gastric or duodenal ulcer. Excessive salivation is common. This may lead to aerophagy, which occasionally causes severe pain in the left hypochondrium owing to inability to expel the excess of gas from the stomach on account of œsophageal spasm (*aërogastrie bloquée*).

An X-ray examination during the swallowing of a barium emulsion generally shows no abnormality, though the emulsion may be held up by spasm at the lower end of the œsophagus. The œsophagus may be slightly dilated, but there is never anything approaching the characteristic mega-œsophagus caused by achalasia of the cardia. When a semi-solid opaque meal is swallowed, or if the opaque emulsion is swallowed whilst the patient is lying down, a characteristic picture is obtained. This consists of a narrowing caused by spasm near the lower end of the œsophagus; below this is a rounded shadow corresponding with the crater of the ulcer, and below this again is the normal cardiac sphincter, in which two or three longitudinal folds can often be recognised, passing to the stomach, a small portion of which is frequently above the diaphragm and separated from the rest of the stomach by a narrow neck.

It is sometimes advisable to confirm the diagnosis by œsophagoscopy, though occasionally the ulcer itself cannot be reached owing to the spasm just proximal to it. If there is any doubt about the nature of the ulcer, a fragment of its margin should be removed for microscopical examination. The ulcer is always associated with inflammation of the mucous membrane of the lower third of the œsophagus.

Diagnosis.—The diagnosis of peptic œsophageal ulcer must be made from a consideration of the symptoms, as the condition is generally missed in a routine radiological examination. The latter, however, serves to exclude achalasia of the cardia and cancer of the œsophagus, which might be regarded as the cause of the dysphagia, though substernal pain and heartburn are never present in achalasia.

Ulcer of the œsophagus is clinically indistinguishable from acid œsophagitis affecting the lower end of the œsophagus; the latter may be associated with spasm, but no actual ulcer can be recognised either with the X-rays or the œsophagoscope. I have seen two cases in which the œsophagus was divided into three distinct segments by a constant spasm at three different points, which was, however, insufficient to prevent the easy passage of an œsophagoscope.

Treatment.—A patient with œsophageal ulcer should be given a pint of citrated milk and ½ oz. strained orange juice 4 times a day without any of the thick feeds which can be safely used in cases of gastric and duodenal ulcer. He should sit up all day and have the head of his bed raised by blocks so as to prevent stagnation in the lower end of the œsophagus, and he should drink a few ounces of water a quarter of an hour after each feed so as to wash its remains into the stomach. Maximal doses of atropine and a tablespoonful of olive oil should be given a quarter of an hour before each feed in order to overcome spasm. The treatment should be continued until not only all pain and dysphagia have disappeared, but also until the X-rays show no trace of a crater and the occult blood has disappeared from the stools. If the ulcer

does not heal within a couple of months, or if, when first seen, much cicatricial narrowing with secondary stasis in the œsophagus is present, a gastrostomy should be performed without further delay. When the ulcer has completely healed, any stenosis which may be present should be treated by dilatation with graduated bougies (*infra*).

In peptic œsophagitis without ulceration the spasm can generally be quickly overcome by the passage of graduated mercury bougies. The patient should be dieted as if he had an œsophageal ulcer, but much less prolonged treatment is required.

NON-MALIGNANT STRICTURE

Ætiology.—Stricture of the œsophagus is in rare cases congenital; the middle part of the œsophagus may be represented by a fibrous cord, or the lower part may open into the trachea or into one of the bronchi. It may also be a sequel of the acute œsophagitis resulting from caustic poisoning or the impaction of a foreign body and of the healing of a chronic ulcer just above the cardiac sphincter.

Treatment.—Fibrous strictures must be dilated by the passage of bougies of gradually increasing size. They should be guided into the stomach by a piece of string, previously swallowed, threaded through a metal slide at their lower end. There is a constant tendency to recur, so a mercury bougie must be passed at regular intervals. In acquired cases in which the origin is obscure, the Wassermann reaction should be tested; if it is positive, anti-syphilitic treatment may produce much improvement, though dilatation by bougies is generally required as well.

CANCER OF THE ŒSOPHAGUS

Ætiology.—Cancer of the œsophagus occurs with about one-third the frequency of cancer of the stomach. Over 70 per cent. of all cases occur in men, but 80 per cent. of upper œsophageal growths occur in women (p. 547). Among 100 cases of cancer occurring in the alcohol trades (barmen, cellarmen, waiters and brewers) about 15 affect the œsophagus compared with 7 in men working in other trades, showing that the chronic œsophagitis caused by excessive indulgence in alcohol is a predisposing cause of cancer of the œsophagus.

Pathology.—Most growths of the œsophagus are epitheliomata. They are most common in the lower end and then at the level of the bifurcation of the trachea, these being the narrowest parts, the mucous membrane being consequently most subjected to friction by coarse food. Less frequently they occur at the upper end of the œsophagus; it is then impossible to say whether an epithelioma is a primary growth of the pharynx, from which it has spread into the œsophagus, or a primary growth of the œsophagus which has spread into the pharynx. Ulceration occurs at an early stage. Accumulation of food in the œsophagus above the obstruction leads to progressive dilatation, and the efforts of the œsophageal musculature to overcome the obstruction results

in hypertrophy, but the dilatation and hypertrophy are comparatively slight except in cancer of the lower end, as when the obstruction is higher up, vomiting occurs so quickly that very little food can accumulate.

Symptoms.—Dysphagia is almost always present, and is the first symptom in a large majority of cases. Most frequently a patient in perfect health one day experiences a slight discomfort on swallowing; soon he notices that his food seems to stick for a moment before passing on into his stomach. The difficulty becomes slowly but steadily more marked, with rare intermissions lasting for a few meals or at most for a few days. The patient often manages to swallow his food by chewing more thoroughly, by taking smaller mouthfuls, and by drinking after each mouthful; but more and more effort is required, until after a period, which is generally between 1 to 4 months but may be as long as a year, solid food ceases to pass at all and is regurgitated into the mouth a few seconds later. The patient generally localises the position of obstruction correctly, but owing to a protective reflex spasm or achalasia of the pharyngo-œsophageal sphincter he sometimes thinks that it is in the upper end when it is really in the lower third. The difficulty in swallowing continues, until after an average of 8 months there is complete obstruction to the passage of fluids as well as solids.

Pain occurs in only 40 per cent. of cases; it is most frequently absent when the growth is in the lowest third of the œsophagus. It occasionally begins a few days before or simultaneously with the dysphagia, but more commonly it is not noticed until the latter has been present for 1 or 2 months. The pain may be present only during deglutition, disappearing as soon as the food passes the obstruction. It is situated at the level of the obstruction and often passes through to the back.

Regurgitation of food almost always occurs sooner or later; it generally begins between 1 and 2 months after the onset of symptoms and is rarely delayed as long as 6 months. When the growth is situated in the upper third of the œsophagus the food is violently ejected out of the mouth or even from the nose after a coughing effort. When the middle or lower third is involved, the food regurgitates without effort into the mouth, often immediately after meals. If the œsophagus is dilated, food may be regurgitated any time up to 2 hours after being swallowed. The food is completely undigested and always contains mucous saliva, often in considerable quantity. Regurgitation of saliva alone occurs when the obstruction is sufficient to interfere with the swallowing of fluid as well as of solid food. Salivation may be continuous. The regurgitation of the contents of the dilated œsophagus gives relief to any discomfort or pain which is present at the time. The regurgitated material sometimes contains blood and pus, and may be very foul; occasionally several ounces and, in rare cases, a large quantity of blood is vomited.

Progressive emaciation occurs owing to the small amount of food which is taken, and when obstruction is complete the loss of weight is very rapid. The appetite may remain good, and hunger may be very distressing in the early stages, but this becomes less marked as the disease progresses. Severe thirst with dryness of the mouth is sometimes present, and fetid breath is common when there is extensive ulceration. In the late stages small hard glands are often felt in the neck, especially just above the inner end of the clavicle and beneath the lower jaw.

The vagus or recurrent laryngeal nerves, especially of the left side, may be involved, and one, or rarely both, vocal cords may consequently be paralysed. Pressure on the cervical sympathetic may cause contraction of the pupil with slight enophthalmos and narrowing of the palpebral fissure on the affected side. Compression of the trachea or the main bronchi by the tumour or by secondary glands may cause hoarseness, coughing and dyspnœa. Perforation into the trachea or a bronchus gives rise to a paroxysm of coughing and dyspnœa whenever food is swallowed, and death from broncho-pneumonia or gangrene of the lung is likely to occur. Perforation into the pleural cavity may produce an empyema, but a serous pleural effusion may develop without perforation.

Diagnosis.—In a large proportion of cases it is possible to make a definite diagnosis from the history and from the information obtained with the X-rays, which should always be used without delay in cases of dysphagia. Before giving the opaque meal the thorax should be examined from every direction in order to exclude an aneurysm, although in the very rare cases in which this causes dysphagia other more characteristic symptoms generally make the diagnosis clear. Occasionally a growth of the œsophagus or secondary glands throw a shadow with the X-rays, but this is rarely obvious until the symptoms have been present for a considerable time. With an opaque meal the X-rays show the position and length of any narrowing of the lumen of the œsophagus, the degree of dilatation above the obstruction and the amount of obstruction, but the latter may be in part caused by spasm. In the earliest stages, when the lumen is not much reduced, the semi-fluid opaque meal may pass down without revealing any abnormality. Some ordinary food which is known to cause pain or difficulty should then be swallowed with the opaque fluid; spasm is induced and the position and extent of the growth can be clearly recognised.

The diagnosis of a growth of the cardia from achalasia has already been considered (p. 549). The presence of hard glands in the neck makes the diagnosis of cancer extremely probable. In the rare cases in which the history and the X-rays leave the diagnosis in doubt, and especially in early cases, an examination should be made with the œsophagoscope, by means of which the nature of the obstruction can generally be recognised, and a fragment removed for biopsy, though failure to detect malignant disease in the excised fragment does not exclude the possibility of cancer.

There may be considerable difficulty in diagnosing between an epithelioma of the lower end of the œsophagus, which spreads upwards, but very rarely downwards into the stomach, and a primary carcinoma of the fundus of the stomach, which almost invariably involves the cardiac orifice sooner or later. With the former the dysphagia is the first symptom; with the latter anorexia, pain after food, loss of weight and strength, vomiting and increasing pallor may appear before the dysphagia, but this is not always the case, as dysphagia may be the only symptom. When the tumour is gastric in origin the X-rays show a filling defect, together with irregularity of the folds of mucous membrane and encroachment on the transparent arc which is normally formed by the gas in the fundus, and sooner or later a mass can be felt high up under the left costal margin.

Prognosis.—Death occurs between 2½ months and 2½ years after the onset of symptoms, the most common period being between 6 and 12 months.

It is most frequently due to broncho-pneumonia, exhaustion from starvation being the next most common cause.

Treatment.—The radical treatment of cancer of the œsophagus by excision of the growth has very rarely been successful. In recent years great advances have been made in treatment by radiotherapy. Though I have not seen any cases which could be regarded as cured, dysphagia has completely disappeared and the patient has been able to eat ordinary food and lead an active life for many months. Two different methods may be tried, and in some cases when the symptoms return after one the other can be safely used. The first is by means of maximal doses of deep X-rays given from different angles. The usual dosage is much too small, but when only just insufficient to produce anæmia and burning of the skin is given, rapid improvement follows. The other method is by the direct implantation of radon seeds through an œsophagoscope. When the growth is so long that the lower end cannot be reached, additional seeds can be implanted from below through an œsophagoscope introduced through an opening in the stomach.

With the modern forms of radiotherapy it is now rarely necessary to insert tubes, but if obstruction in the middle of the œsophagus is not overcome, a spiral metal tube should be introduced through an œsophagoscope, if necessary after preliminary dilatation of the stricture by bougies. Its lower end reaches beyond the growth, whilst the upper funnel-shaped end rests on its proximal margin. The tube can be left *in situ* until the end, but it sometimes leads to so much dilatation that it passes through the obstruction and is expelled *per anum*.

So long as any obstruction is present the food should be semi-fluid or fluid, and should be taken in small quantities at frequent intervals. Some patients are able to swallow raw eggs whole. As large a dose of atropine as possible short of producing unpleasant symptoms given half an hour before each feed and a dessertspoonful of olive oil just before often help its passage through the stricture.

Gastrostomy is required only in the comparatively rare cases in which sudden complete obstruction occurs before there has been time for radiotherapy to be applied and a tube cannot be introduced owing to the growth being at the upper or lower extremity of the œsophagus.

ARTHUR F. HURST.

DISEASES OF THE STOMACH

INTRODUCTION

I. FUNCTIONS OF THE STOMACH

Until recently little attention was paid to any of the functions of the stomach except that concerned with the digestion of proteins. It is now realised that several other functions are of equal or even greater importance from a clinical point of view.

(*a*) *Digestion.*—The pepsin of the gastric juice digests proteins in the presence of free hydrochloric acid. Its activity rapidly falls when the amount of free acid present sinks below 0·08 per cent. until it finally ceases in complete achlorhydria, even if hydrochloric acid is still present in organic combination. In spite of this digestion of proteins remains unimpaired in achlorhydria, as the trypsin of the pancreatic juice is capable by itself of digesting all the proteins consumed in ordinary meals. An increase in the free hydrochloric acid above the average normal does not lead to any increase in peptic activity.

(*b*) *Protection of the small intestine from injury.*—An important function of the stomach is to protect the small intestine from thermal, chemical and mechanical irritants. Very hot and very cold food and drink are brought to the body temperature; the gastric juice dilutes chemical irritants, such as alcohol, and softens hard particles, and the churning movements in the pyloric vestibule break up lumps of insufficiently chewed food. At the same time the stomach, like all other mucous membranes, attempts to protect its own mucous membrane from damage by secreting mucus in response to stimulation by chemical and mechanical irritants.

(*c*) *The antiseptic acid barrier of the stomach.*—The free hydrochloric acid of the gastric juice is a very efficient germicide and rapidly destroys streptococci swallowed from the mouth, throat and nose, as well as organisms present in contaminated food and drink, such as those of typhoid fever and bacillary and amœbic dysentery. It also helps to keep the reaction of the small intestine at a level which prevents its invasion by *B. coli* from the lower ileum and colon.

(*d*) *Influence on the blood and spinal cord.*—The gastric juice contains an enzyme, hæmopoietin, the "intrinsic factor" of Castle, which acts on something present in protein food, the "extrinsic factor," to produce a substance which is stored in the liver and is the normal stimulant for the formation of red corpuscles by the bone marrow. It is produced by the glands of the pyloric end of the stomach and the duodenum, but not by those of the body of the stomach, the chief and parietal (oxyntic) cells of which secrete pepsin and hydrochloric acid respectively. The gastric juice also contains an enzyme, neuropoietin, which is produced by the same glands and acts in the same way as hæmopoietin to form a substance which is essential for the nutrition of the central nervous system.

The presence of free hydrochloric acid helps the conversion of the iron contained in food into a form in which it is easily absorbed so as to become available for the production of hæmoglobin.

II. GASTRIC DIATHESES

The anatomy and physiology of the stomach of 80 per cent. of healthy people are so well adjusted to the exigencies of ordinary life that they are likely to reach old age without ever suffering from any chronic gastric disorder. Of the remaining 20 per cent. approximately one-half are born with a *hypersthenic gastric diathesis*, and most of the other half are born with a *hyposthenic gastric diathesis*, both of which are often familial. The former have hyperchlorhydria, which is often, though not invariably, associated with a short, high, rapidly emptying stomach. The latter have hypochlor-

hydria, which is generally associated with a long, low, slowly emptying stomach. Both constitutions are compatible with perfect health, but under unfavourable conditions each predisposes to the development of special symptoms and special organic diseases. The hypersthenic stomach is capable of secreting very little mucus compared with the hyposthenic stomach, whether in response to mechanical, thermal and chemical irritants or as a result of gastritis.

Complete achlorhydria is present in about 3·5 per cent. of healthy children and young adults of both sexes, but it is still uncertain whether this is congenital and a result of an inborn error of secretion—a true constitutional achylia, or whether it is acquired as a sequel of gastro-enteritis or some general infection in infants or young children with an extreme degree of constitutional hypochlorhydria.

III. CAUSES OF GASTRIC DISORDERS

A.—Organic

(i) *Mechanical, chemical and thermal irritants.*—The mouth acts as the first line of defence in protecting the alimentary tract from damage by swallowed irritants. Food and drink are brought to the body temperature, chemical irritants are diluted, lumps of food are broken up by chewing and are intimately mixed with saliva, which softens hard particles and coats insoluble ones with mucus. A man with good and sufficient teeth, who takes the trouble to use them and avoids grossly indigestible food and excess of alcohol, need not swallow anything until its thermal, chemical and mechanical properties have been so altered that it will cause no irritation when it comes into contact with the gastric mucous membrane. But many people bolt their food before it has been thoroughly masticated, whilst others have insufficient teeth and inadequate dentures, with the result that the stomach is daily subjected to mechanical, chemical and thermal irritants. It is also often damaged by excessive indulgence in alcohol, and especially by taking cocktails and spirits whilst fasting, when even a small quantity acts as a powerful irritant. Strong tea and coffee, mustard, pepper, curry, pickles, and excess of totally indigestible raw vegetable matter, taken in the mistaken idea that plenty of "roughage" is good for the health, may have the same effect. The stomach is frequently irritated by the unconscious swallowing of the "juice" of tobacco smoked in excess, especially when the stomach is empty. Many people injure their gastric mucous membrane by taking drugs, often quite needlessly, for supposed constipation, rheumatism, and other self-diagnosed complaints, quite apart from those used in the treatment of definite chronic maladies, such as aspirin, bromides, iodides, digitalis, mercury, creosote and quinine. The contents of the duodenum act as irritants when introduced into the stomach; gastritis is consequently a frequent sequel of gastro-jejunostomy and partial gastrectomy.

I have already described how the stomach acts as a second line of defence for protecting the small intestine from mechanical and chemical irritation. But it is itself liable to suffer in the attempt in spite of the mucus it secretes with the object of protecting itself from damage, especially if the first line of defence is deficient owing to bolting of food or inadequate teeth. In the

80 per cent. of people with an average type of stomach it generally proves successful. In the 10 per cent. with constitutional hypochlorhydria and achylia the second line of defence is deficient; they are consequently very likely to develop gastritis and in most cases the hypochlorhydria sooner or later gives place to achlorhydria. In the 10 per cent. with hyperchlorhydria there is ample protection against mechanical irritants, and also against chemical irritants if taken when the stomach is full. But as hyperchlorhydria is generally associated with rapid evacuation, the stomach is empty for a much larger proportion of the day and night than in the average individual, so that there is more opportunity for the mucous membrane to be damaged by alcohol, tobacco and drugs. When gastritis has once developed in an individual with constitutional hyperchlorhydria, the abnormally vulnerable mucous membrane is likely to be further irritated by the excessive acidity of the gastric juice, which is completely without effect on the normal gastric mucous membrane.

(ii) *Infection.*—Infected material is constantly swallowed by people with pyorrhœa alveolaris, infected tonsils, chronic pharyngitis and sinusitis, and by children with adenoids. In achlorhydria the antiseptic acid barrier of the stomach is lost, and streptococci from the mouth invade the stomach and irritant toxins are likely to form in the gastric contents. When gastric juice is secreted in normal or excessive quantities, and even when it is deficient in hypochlorhydria, swallowed bacteria are rapidly destroyed. When hyperchlorhydria is associated with a rapidly emptying stomach, the unconscious swallowing of infected material from the mouth, nose and throat may infect an erosion or ulcer of the gastric or duodenal mucous membrane during the many hours in which it is not protected by the presence of gastric juice.

(iii) *Hæmatogenous irritants.*—Many acute infections may be accompanied by acute gastritis, which is often followed by chronic gastritis. The gastritis is due mainly to the direct action of bacterial toxins conveyed in the blood to the gastric mucous membrane, which perhaps makes an attempt to excrete them. Possibly the toxins produced in the body tissues themselves in acute infections may be in part responsible, just as the toxins of uræmia and those produced in the skin in extensive burns may cause gastro-duodenitis and acute ulcers. The abdominal symptoms in gastric influenza are the result of acute gastritis, and acute ulcers and erosions are common in the stomach and duodenum in fatal cases of a great variety of infections.

The causes of gastritis are so numerous and so common that few people can pass through life without being subjected to one or more of them. The 80 per cent. of individuals with the average normal stomach are so well protected that they are less liable to develop gastritis as a result of these insults, but probably few of those with constitutional hyperchlorhydria and constitutional hypochlorhydria escape.

B.—Functional

Exhaustion from physical or mental overwork, insufficient sleep, prolonged residence in the tropics, insufficient food, and from the toxæmia of chronic infections, such as phthisis, and acute infections, such as influenza, has a depressing effect on all bodily functions and at the same time it tends to increase the

irritability of the visceral nervous system. This *faiblesse irritable* gives rise to symptoms in an organ, the physiological and anatomical functions of which are less efficient than the average. Consequently it is only individuals with the hypersthenic and hyposthenic gastric diatheses who are likely to develop gastric symptoms as a result of exhaustion. Their symptoms are then very similar in character to those produced by the organic diseases which may be associated with these diatheses.

Depressing emotions and the psychological factors concerned in the production of the anxiety neuroses may also give rise to similar gastric symptoms in the predisposed. They may also be important factors in the actual development of organic diseases, especially gastric and duodenal ulcer. Anxiety is a common cause of recurrences and of the sudden increased activity of ulceration which may result in hæmorrhage or perforation.

C.—Reflex

Disorders of other abdominal organs may give rise to reflex gastric symptoms in individuals with the hypersthenic gastric diathesis and, less frequently, in those with the hyposthenic gastric diathesis. Thus chronic cholecystitis, recurrent subacute appendicitis, diseases of the colon and even simple constipation may give rise to reflex gastric symptoms.

IV. EFFECT OF GASTRITIS ON GASTRIC SECRETION

The functional activity of an organ is always reduced when it is inflamed. At the onset of acute gastritis no gastric juice is secreted. In chronic gastritis the secretion is reduced to an extent which varies with the severity and the duration of the inflammation, the actual amount of free acid present in the stomach in a test-meal depending upon the constitutional type of stomach in each individual. Thus the hyperchlorhydria of individuals with the hypersthenic gastric diathesis becomes less extreme or may be replaced by a normal curve of acidity or even, in exceptional cases, by hypochlorhydria. This is well seen in the gastritis accompanying chronic ulcer: when medical treatment has resulted in the healing of the ulcer and the disappearance of the gastritis, the acidity is almost always higher than it was before.

The hypochlorhydria of individuals with the hyposthenic gastric diathesis is in most cases eventually replaced by complete achlorhydria, which can generally be overcome by treatment (p. 585). The reduction in acidity in these cases is mainly due, as it is in hyperchlorhydria, to the effect of the inflammation on the activity of the secreting glands, but it is increased as a result of the excessive secretion of mucus which accompanies the inflammation. The mucus acts partly by its mechanical action in blocking the mouths of the secreting tubules and partly by its chemical action in combining with some of the free acid. The neutralising effect is, however, slight and due almost entirely to the sodium bicarbonate it contains and not to its own buffer action, as it almost completely disappears after the salt has been separated by dialysis. When free acid does not return as a result of treatment the gastritis has presumably led to a profound degree of atrophy of the gastric mucosa.

It is clear that gastritis associated with high or normal acidity, so-called

acid gastritis, is not an early stage of gastritis associated with achlorhydria, nor is the former a result of prepyloric gastritis and the latter of fundus gastritis. Both are due to the same causes, the amount of free acid present depending upon the constitution of the individual concerned.

V. RESULTS OF HYPERCHLORHYDRIA

I have already pointed out that hyperchlorhydria tends to protect the stomach from irritation when the first line of defence is inadequate. But the deleterious effect of friction on the mucous membrane of the distal half of the stomach when hard or large pieces of food are swallowed continues, and irritation by alcohol, tobacco and drugs may occur during the many hours in which the stomach is empty. If even a mild degree of gastritis is produced as a result of this, the mere presence of hyperchlorhydria is likely to aggravate it, as, although hyperchlorhydria is not itself a pathological condition, the excessive acidity of the gastric juice is a potential danger. The healthy mucous membrane is always bathed in gastric juice and is neither digested by its pepsin nor irritated by its free hydrochloric acid. After death, however, the mucous membrane is rapidly digested. During life localised necrotic areas may also undergo digestion, and this may perhaps also occur in areas in which the circulation is temporarily arrested or very deficient before actual necrosis has occurred. As peptic digestion is no more active with 0·3 per cent. than with 0·08 per cent. free hydrochloric acid, such digestion is not specially likely to occur in the presence of hyperchlorhydria. But although the living mucous membrane even when abnormally vulnerable as a result of gastritis can never undergo peptic digestion, it is very likely to be damaged by free hydrochloric acid if present in a strength greater than the average. The likelihood of this is still greater when the hyperchlorhydria is associated with hypersecretion, as unusually strong acid continues to be secreted in the absence of food, which under ordinary conditions dilutes it and partially neutralises it. In the extreme forms of constitutional hyperchlorhydria the stomach secretes acid throughout the night, so that undiluted gastric juice comes into contact with the mucous membrane of the stomach and duodenal bulb for 9 or 10 hours. Moreover, owing to the deficient power of secreting mucus, which is a characteristic of the hypersthenic stomach, the protection against damage afforded by a layer of mucus in the hyposthenic stomach is absent. In the conditions already described, in which the failure of the first line of defence gives rise to chronic gastritis, the excessive acid in hyperchlorhydria gives the gastritis certain characteristics which are absent from that associated with hypochlorhydria and achlorhydria. Biopsies and gastroscopic investigations have shown that it is very frequently associated with minute erosions, some of which may develop into acute ulcers, which may in turn become chronic ulcers. The condition may therefore be called ulcerative gastritis. When the hyperchlorhydria is associated with the rapidly emptying, short, high stomach, which is often a feature of the hypersthenic gastric diathesis, the duodenal bulb is equally involved, the condition thus being one of ulcerative gastro-duodenitis, in which a chronic ulcer is most likely to develop in the duodenum. When, on the other hand, the hyperchlorhydria is associated with a long, low, slowly emptying stomach, the main stress falls upon the stomach : the gastritis is likely to be more severe

and a gastric ulcer may develop, whilst the duodenum is spared. At the same time the gastric stasis leads to more prolonged contact of the entire gastric mucous membrane with any irritants it may contain, so that, although the distal half of the stomach is still the part most severely inflamed, the fundus is more affected than with a rapidly emptying stomach. Consequently the power of secreting acid by the fundus glands may be directly impaired and their stimulation may be reduced owing to the deficient production of the gastric hormone by the antral mucous membrane in response to chemical stimulation. In gastric ulcer the hyperchlorhydria which is at first present thus tends to be more or less reduced, and in very chronic cases hypochlorhydria, and in rare cases even achlorhydria, may result. With treatment, however, the acidity always rises, though sufficient permanent damage may have taken place to prevent a return to the original hyperchlorhydria.

Owing to the familial incidence of the hypersthenic gastric diathesis, it is common for gastric or duodenal ulcers to occur in several members of the same family.

Chronic gastric or duodenal ulcers or scars of such ulcers are found in about 10 per cent. of all autopsies, this being also approximately the number of healthy young adults with hyperchlorhydria. It would appear, therefore, that an individual with the hypersthenic gastric diathesis is almost certain sooner or later to develop an ulcer. It is true that hyperchlorhydria may no longer be present when a test-meal is given, especially in the case of a gastric ulcer, but it was probably present when the ulcer first formed, perhaps many years earlier, and has since been masked by the coexistent chronic gastritis.

VI. RESULTS OF HYPOCHLORHYDRIA AND ACHLORHYDRIA

The incidence of achlorhydria among healthy people rises from 4 per cent. at the age of 20 (Bennet and Ryle), to 8 per cent. in the 30–39 period, and 12 per cent. in the 40–49 period, but in the next three decades taken together there is a further rise of only about 4 per cent. It can thus be concluded that all or very nearly all of the individuals with the hyposthenic gastric diathesis as well as a few with normal acidity eventually develop achlorhydria as a result of gastritis.

Gastritis with achlorhydria generally gives rise to no gastric symptoms, though it may occasionally produce a mild form of chronic indigestion, and it is a not uncommon cause of nausea.

In achlorhydria the excess of mucus is a poor substitute for gastric juice, and the consequent loss of the second line of defence leads to irritation of the small intestine, so that duodenitis and enteritis develop in addition to the gastritis. The mechanical and chemical irritation of the intestines explains why achlorhydria is a common cause of chronic and recurrent diarrhœa.

Swallowed bacteria flourish in the alkaline contents of the stomach and pass into the duodenum, which is normally sterile, but now swarms with bacteria. The increased alkalinity of the intestinal contents allows bacteria which are normally confined to the colon to ascend the small intestine as far

as the duodenum and stomach, both of which contain colon bacilli from the large intestine even more frequently than streptococci from the mouth.

Chronic cholecystitis is generally a result of a *B. coli* infection which ascends from the duodenum by way of the common bile duct and cystic duct to the gall-bladder. This is especially likely to occur when achlorhydria is present. As gall-stones are generally secondary to cholecystitis, it is not surprising that achlorhydria occurs in about 50 per cent. of cases.

Achlorhydria is also a very important predisposing cause of intestinal infections, such as typhoid and paratyphoid fever, bacillary and amœbic dysentery and cholera, the organisms of which are rapidly destroyed by the normal gastric juice, and its presence is therefore a constant source of danger in individuals residing in tropical countries.

The toxæmia which follows the intestinal infection resulting from achlorhydria is one factor in about 35 per cent. of cases of rheumatoid arthritis and in some cases of asthma, skin diseases and other conditions associated with allergy, especially in children. Flushing of the face during meals is common in achlorhydria, and achlorhydria or hypochlorhydria is generally present in rosacea.

VII. EFFECTS OF GASTRITIS ON HÆMATOPOIESIS AND THE NUTRITION OF THE CENTRAL NERVOUS SYSTEM

The absence of free acid from the gastric contents in achlorhydric chronic gastritis and the enteritis with which it is often associated may interfere with the assimilation of the iron in food, so that in individuals who take a diet, in which there is only just enough iron for the needs of the body under the most favourable conditions, a simple achlorhydric anæmia develops, which differs from pernicious anæmia in occurring almost exclusively in women and in being curable by large doses of iron, whilst liver and stomach extract are entirely without effect.

Achlorhydria is found in about 99 per cent. of cases of pernicious anæmia and of subacute combined degeneration of the spinal cord, though it is not the actual cause of it, the absence of hydrochloric acid from the gastric secretion being associated with the absence of the hæmopoietin and neuropoietin, required for the production of the natural stimulant of hæmatopoiesis, and of the substance required for the normal nutrition of the central nervous system respectively. The gastritis is the primary condition; there is consequently often a history of chronic diarrhœa or other symptoms to which it has given rise dating from months or years before the onset of anæmia or nervous symptoms, and in several cases the achlorhydria has been known to exist during this time. The frequent occurrence of pernicious anæmia and subacute combined degeneration of the cord in more than one member of a family is due to the familial occurrence of constitutional achylia gastrica and hypochlorhydria, which may depend upon a primary atrophy of the gastric mucosa. Moreover, achylia is often present without any abnormality of the blood or central nervous system in relatives of patients with these diseases.

The first function of the gastric mucous membrane to suffer in gastritis is the secretion of hydrochloric acid. Consequently in the majority of cases of achlorhydria pepsin is still secreted in normal quantity, the secretion

of mucus is actually increased, and the production of hæmopoietin and neuropoietin is unimpaired. If the exciting cause of the gastritis continues to be at work when complete achlorhydria has developed, the gastritis becomes progressively more severe. After a time the damage to the secreting tubules is so severe that they can never recover their power of secreting acid, even if all active inflammation ceases, and at the same time the secretion of pepsin becomes more or less impaired. The mucus-secreting cells take part in the general atrophic changes of the mucous membrane, so that mucus disappears from the test-meal, its absence being a sign of the severity of the process and not an indication that no gastritis is present. In this advanced stage of gastritis the production of the intrinsic factors required for the normal activity of the bone-marrow and nutrition of the central nervous system, hæmopoietin and neuropoietin, may cease to be formed, and pernicious anæmia or subacute combined degeneration of the cord develops. In a small number of cases this function of the mucous membrane is impaired at an earlier stage; thus in three of my cases of pernicious anæmia the secretion of free acid returned as a result of treatment of the gastritis, and in 1 per cent. of cases pernicious anæmia and subacute combined degeneration of the cord develop whilst free hydrochloric acid is still being secreted.

The hæmatopoietic and neurotrophic functions of the gastric mucous membrane are occasionally destroyed suddenly by an exceptionally severe attack of acute gastritis, the symptoms dating from an attack of food poisoning or an acute infection. Complete and partial gastrectomy, and very rarely the gastritis following gastro-jejunostomy, may have the same effect.

EXAMINATION OF THE STOMACH

I. Motor Functions

(*a*) *Size, shape and position.*—Inspection of the abdomen may reveal the outline of the stomach in thin patients, especially is pyloric obstruction has led to excessive peristalsis. By palpation under similar circumstances the lower border of the stomach can often be felt. Palpation may also reveal the presence of a tumour, the size, shape, position and mobility of which should be estimated. Percussion may give some idea as to the quantity of gas in the stomach, but it cannot help in the determination of its size, shape or position. Auscultatory percussion and friction have been shown by means of the X-rays to be quite valueless for examining the stomach.

The size, shape and position of the stomach can be readily and accurately determined, both in the vertical and horizontal position, by means of the X-rays after a meal of strained gruel containing 4 ounces of barium sulphate. By palpation during the screen examination its mobility can be investigated and the presence of adhesions and areas of tenderness recognised.

(*b*) *Tone.*—Splashing and succussion can be obtained in an individual with relaxed abdominal muscles and a stomach with normal tone. They give no information as to the presence of deficient tone.

Owing to the adaptation of the stomach to the volume of its contents, there is little difference in the upper level of the semi-fluid chyme as seen with the X-rays in the erect position whether the volume is 5 ounces or 2 pints,

and the greater curvature is only slightly depressed as the stomach is gradually filled. When the stomach is hypotonic, this adaptation to the volume of its contents does not occur; the food drops to the most dependent part, the upper level of the contents slowly rising and the greater curvature becoming more dependent as the volume increases. It is important to distinguish this condition from the distension without hypotonus caused by the constant presence of fluid or fluid and food in the stomach when the pylorus is obstructed. The opaque meal then appears to fall to the bottom of a large stomach, but closer investigation shows that it is really falling through a large quantity of fluid already present in the stomach, the upper limit of which can be recognised at the normal distance below the diaphragm. If the examination is repeated after emptying the stomach by means of a stomach tube, its tone and size are found to be normal.

(*c*) *Peristalsis.*—In unusually thin women normal peristalsis is occasionally visible, but in the majority of cases the presence of visible peristalsis indicates organic pyloric obstruction. The patient should be examined immediately after a meal; in doubtful cases peristalsis can be rendered more obvious by massage. At a stage preceding that in which peristalsis is visible, it may sometimes be felt as a periodic hardening if the hand is kept for some time gently pressing upon the right side of the abdomen a little above the umbilicus.

In pyloric obstruction the peristaltic waves can be seen with the X-rays to arise in the fundus instead of in the centre of the stomach and to be unusually deep at a period considerably earlier than that in which they become visible through the abdominal wall. Reversed peristalsis generally indicates organic pyloric obstruction, but I have seen it in cases of lesser curvature ulcer with gastric stasis but no obstruction. Irregular peristalsis, and especially peristalsis which begins in the normal position but disappears and perhaps reappears as it passes along the greater curvature before the pylorus is reached, is very suggestive of malignant infiltration.

(*d*) *Rate of evacuation.*—If splashing can be produced by palpation over the stomach at a time when it should be empty, gastric stasis is probably present. But there are so many possible fallacies that this is of very little value compared with the accurate results obtained with the stomach tube and X-rays. Nothing should be eaten or drunk during the 12 hours preceding a test-meal. The stomach should be completely emptied after the tube has been swallowed before the meal is given. In normal individuals it is uncommon for more than 25 c.c. of colourless or bile-stained gastric juice to be found; the reaction for starch is negative, no gross food residue is present, and even microscopically no meat fibres and only occasionally a little vegetable debris, together with a few leucocytes and bacteria derived from the mouth, are seen. In chronic gastritis a small quantity of thick alkaline fluid, consisting of gastric mucus with swallowed saliva and pharyngeal and œsophageal secretion, is present. In the continuous secretion which results from an ulcer near the pylorus, even in the absence of organic obstruction, a varying quantity of very acid fluid without any food residue is found. When an ulcer has led to organic obstruction, starch granules and vegetable debris, but no meat fibres, are present, in addition to some acid fluid containing starch; the quantity of fluid is much increased if the ulcer is still active, as hypersecretion then occurs in addition to stasis. In malignant obstruction

the gastric contents are thicker and contain debris of both vegetable and animal food; free hydrochloric acid is absent, and lactic acid, together with many bacteria, are present.

If the test-meal is completely evacuated in less than three hours, no organic obstruction can be present. If starch is still present in the 3-hour fraction, the stomach should be completely emptied: a further estimate of the degree of gastric stasis can be made from the volume of starch-containing fluid obtained.

Careful examination with the X-rays before the opaque meal is given may show that a considerable quantity of fluid is present in the fasting stomach; its upper horizontal level can be seen under the gas in the fundus, and splashing can be observed if the patient shakes himself. If the shadow of the stomach is still visible 6 hours after a barium meal, nothing having been taken in the interval, stasis is present; after 9 hours it is probably, after 12 hours it is almost certainly, due to pyloric obstruction.

It is important to remember in connection with both the test-meal and the X-rays that if the patient has a severe headache at the time, any delay in evacuation may be due to the complete cessation of peristalsis which occurs during an attack of migraine.

II. Chemical Functions

The chemical functions of the stomach can only be adequately investigated by means of a test-meal. The old-fashioned test-breakfast is less satisfactory than the modern fractional test-meal, which provides information respecting quantity and character of the resting-juice and post-prandial secretion, the secretory response throughout the period of gastric digestion, the secretion of mucus, the regurgitation of bile and duodenal contents. The patient, who should have taken no food since the previous night, swallows the tube (the best form being Ryle's modification of that introduced by Einhorn) in the morning. The resting-juice is withdrawn and measured, its bile and mucus content noted, and the free and total acidity determined; the presence of gross food residue or a positive starch reaction is diagnostic of pyloric obstruction. After withdrawal of the resting-juice the patient drinks one pint of oatmeal gruel, and small specimens of gastric contents are withdrawn with a syringe at intervals of a quarter of an hour until the stomach is empty. If starch is still present at the end of three hours the stomach is emptied, the volume obtained is measured, and the tube is withdrawn. The free and total acidity in each specimen is estimated. Topfer solution and phenolphthalein being the respective indicators customarily employed. The time of disappearance of the starch, which may precede complete emptying, is determined by adding iodine to the successive samples. The free and total acidity are plotted as curves upon a chart.

If achlorhydria is present, the resting-juice may be examined for lactic acid by Uffelman's reagent (30 c.c. 1 per cent. carbolic acid with a few drops of ferric chloride solution), which it changes from blue to a canary yellow. An ethereal extract of the gastric contents must be used, 5 c.c. of gastric contents being shaken with 30 c.c. of ether.

Microscopical examination of the resting-juice may reveal the presence of red corpuscles. The discovery of leucocytes is only of importance if their

number is obviously in excess of the number present in a specimen of spittle obtained at the same time, or if they reappear without squamous epithelial cells half an hour after thorough lavage. True excess of leucocytes indicates the presence of severe gastritis or carcinoma. When the resting-juice or some or all of the fractions of a test-meal are pink or red owing to the presence of blood, a bleeding ulcer or carcinoma is present. Specks of blood in otherwise blood-free specimens may be due to accidental contamination, but more frequently they indicate an abnormal vulnerability of the mucous membrane such as is present in chronic gastritis.

III. Gastroscopy

The introduction of the flexible gastroscope has removed the dangers from gastroscopy. The instrument can be passed without difficulty in a patient who has been prepared by a preliminary injection of morphine and anæsthetising his pharynx. All parts of the gastric mucous membrane can be inspected with the exception of the fundus and the lesser curvature of the pyloric vestibule.

The chief value of gastroscopy is in the recognition of the different forms of gastritis and of erosions and acute and subacute ulcers, which may cause hæmorrhage, but are never recognisable with the X-rays. It is often helpful in diagnosing the cause of post-operative symptoms when radiology has failed to show anything abnormal, and it affords the only reliable evidence of complete healing of a gastric ulcer (p. 593). It occasionally affords valuable evidence in the early diagnosis of cancer.

Arthur F. Hurst.

FUNCTIONAL DISORDERS OF THE STOMACH

HYPOTONUS: ATONIC DILATATION

The diagnosis of atonic dilatation of the stomach, which is still frequently made, is a survival from pre-radiological days, when it was supposed to be a common sequel of acute infections, malnutrition and neurasthenia. In a hundred consecutive cases of abdominal disorders examined with the X-rays hypotonus was present in six, and in only one of these, in which it was associated with an unusually long stomach, did it have any direct or indirect connection with the symptoms. In no case was it associated with infections, neurasthenia or malnutrition, and in all but one of 15 cases of extreme wasting due to anorexia nervosa (not included in this series) the tone was normal. Severe hypotonus never occurs except as a result of exhaustion of the hypertrophied musculature of the stomach in organic pyloric stenosis.

VOMITING

Ætiology.—(*a*) Central Vomiting.—Vomiting is only rarely under the control of the will. But a person who has vomited a number of times owing to some central, reflex or toxic cause, may suggest to himself that certain

circumstances will invariably cause him to vomit. The hysterical vomiting which results is a common sequel of vomiting due to other causes (p. 578).

Various emotions, especially those of disgust and fear, may result in vomiting, especially in neurotic individuals. It may occur as a result of incidents which subconsciously revive the memory of an emotion which on some particular occasion caused vomiting. Thus a woman who, on one occasion vomited as a result of terror in a railway carriage, subsequently vomited whenever she travelled in a train and after a time in any vehicle, and even in closed places, such as a church, from which she could not readily escape. The vomiting was associated with a vague feeling of fear, but not consciously with the incident which was the primary cause.

Certain organic nervous diseases, such as cerebral tumour and meningitis, are frequently accompanied by vomiting, which may also occur in compression and in concussion caused by injury. This is generally due to increased intracranial pressure, and in cerebral tumour the relief of intracranial pressure by trephining often leads to cessation of vomiting. A mid-cerebellar tumour may give rise to vomiting as a result of direct pressure on the vomiting centre in the floor of the fourth ventricle long before any other symptoms develop.

The vomiting in migraine is also of central origin. The cyclical vomiting of children is generally associated with a family history of migraine and is often followed by true migraine in adult life, but biochemical factors may play an important part in its pathogenesis, as it is generally controlled by the administration of glucose.

Attacks of vomiting, with or without nausea, but unaccompanied by any pain or discomfort in the abdomen, are generally of central origin. This is all the more likely to be the case if they are associated with headache.

(*b*) Reflex Vomiting.—Vomiting may result from a local or central reflex. The former is the most common of all causes of vomiting. It occurs when the gastric mucous membrane is irritated by poisons, whether introduced in the food or resulting from bacterial decomposition. Gassing was a common cause of vomiting in the War of 1914–1918, some of the irritant gas being dissolved in the saliva, which was secreted in excess and then swallowed. Overdistension with food, especially if it occurs rapidly, as when a big meal is bolted, or if it continues for an abnormally long period as a result of pyloric obstruction, has the same effect. In all these cases more or less relief to the local symptoms results from vomiting.

Painful stimulation of any afferent nerves, but particularly those of abdominal viscera, such as occurs in attacks of pain associated with gastric ulcer, in biliary and renal colic, in Dietl's crises, and in intestinal obstruction, often causes vomiting as a result of a central reflex. Tickling the fauces is a common method of inducing vomiting.

Sea-sickness and air-sickness are caused by a reflex arising from excessive stimulation of the semicircular canals. The vomiting in diseases of the ear in which the semicircular canals are directly or indirectly involved, as in Ménière's syndrome, is of similar origin. The vomiting of early pregnancy is probable reflex; when persistent, it is, I believe, always hysterical and curable by psychotherapy (p. 579).

(*c*) Toxic Vomiting.—Some emetics, such as apomorphine, cause vomiting by direct irritation of the vomiting centre. Other emetics, such as warm water containing salt and copper and zinc sulphate, act reflexly from the

stomach and are consequently only effective when they are swallowed, whilst tartar emetic, ipecacuanha and general anæsthetics, act in both ways.

Poisons produced in the body, as in uræmia, hyperthyroidism and Addison's disease, may irritate the vomiting centre. In uræmia, however, the action is partly reflex owing to the excretion into the stomach of toxins which should be excreted by the kidneys and partly a result of increased intracranial pressure. The bacterial toxins in acute infections, especially gastric influenza, often excite vomiting by their irritant action on the gastric mucous membrane. Toxic vomiting differs from central vomiting and some cases of reflex vomiting in being almost invariably preceded by nausea.

The consumption of certain foods to which a predisposed individual is sensitised may give rise to attacks of " abdominal allergy," in which vomiting is often a prominent symptom (*vide* p. 751).

Treatment.—The proper treatment of vomiting is to remove the cause. In toxic cases and in those due to reflexes from the stomach itself, complete evacuation by a stomach tube gives relief. As purely symptomatic treatment, the most useful drugs are dilute hydrocyanic acid, 3 to 6 minims of which should be given in 60 minims of water, and chlorbutol, 5 grains of which can be given in a cachet and repeated, if necessary, three or four times at intervals of 2 hours. Sea-sickness and air-sickness can generally be prevented by taking $2\frac{1}{2}$ grains each of phenacetin and soluble barbitone half an hour before and again shortly after starting on the journey.

REGURGITATION, HEARTBURN AND WATERBRASH

Regurgitation.—Regurgitation of unaltered food mixed with more or less saliva occurs with pharyngeal diverticula and in œsophageal obstruction resulting from achalasia of the cardia and simple and malignant stricture. Regurgitation of small quantities of partially digested food into the pharynx and less often into the mouth without effort and without nausea occurs in various forms of dyspepsia; its acidity produces a scalding sensation in the pharynx. Regurgitation is frequently associated with flatulence due to aerophagy, the unsuccessful efforts made by the patients to bring up wind when no excess is present in the stomach resulting in regurgitation of some of its fluid contents. The regurgitation may later give place to vomiting, both the regurgitation and vomiting being to a great extent under voluntary control.

Heartburn.—When the indigestion which gives rise to regurgitation is a result of some swallowed irritant such as excess of condiments, alcohol, tobacco or drugs, the gastritis, which is the cause of the indigestion, is likely to be associated with œsophagitis. Apart from this, constant regurgitation of acid food through the œsophagus into the pharynx or mouth leads to œsophagitis. In whichever way the œsophagitis is caused, the œsophageal mucous membrane, which is normally insensitive to dilute hydrochloric acid, becomes sensitive, so that the acid gastric contents produce a sensation of burning behind the sternum when regurgitation occurs. This burning sensation is known as heartburn, and may occur with or without regurgitation into the pharynx and mouth.

Waterbrash.—Waterbrash may occur in any of the conditions which give

rise to ptyalism (p. 529), but most commonly with duodenal ulcer. At a certain interval after a meal, which varies in different cases, but is fairly constant for each individual, an uncomfortable sensation of constriction, which may amount to severe pain, is felt deeply beneath the lower end of the sternum. This may be accompanied by profuse salivation, which is sometimes accompanied by pain in the jaws from the rapid swelling of the parotid glands. Relief occurs on bringing up a few mouthfuls of clear fluid, which is generally described by the patient as being like water, though it sometimes contains a good deal of mucus. The fluid rises into the mouth with little or no effort and without nausea. It comes from the œsophagus and not from the stomach, as even when the previous meal was large and finished less than an hour before, no food is present in the regurgitated material, which is alkaline in reaction and has all the characters of pure saliva. When the flow of saliva is excessive, it runs down the œsophagus without the patient's knowledge and without the aid of actual swallowing; the cardiac sphincter being closed, the fluid collects in the lower end of the œsophagus.

The morning vomiting of alcoholic individuals is the result of a similar process, though it is accompanied by more violent vomiting efforts. In this case the fluid consists of saliva with a considerable proportion of pharyngeal and œsophageal mucus, secreted as a result of chronic pharyngitis and œsophagitis.

Treatment.—No special treatment is required for regurgitation, heartburn and waterbrash beyond that of the primary condition. The momentary discomfort caused by regurgitation and heartburn can be overcome by drinking water or sodium bicarbonate solution, or by chewing and then swallowing an alkaline tablet.

ANOREXIA

Anorexia, or loss of appetite, occurs in a small proportion of cases of chronic gastritis and in the majority of cancer of the stomach, in which it may be the first symptom, but never in uncomplicated gastric or duodenal ulcer. It is common in toxæmic conditions, such as acute fevers and tuberculosis. It is often present when for any reason the tongue is dry or furred.

ANOREXIA NERVOSA

Ætiology.—Anorexia nervosa occurs in adolescents and young adults of both sexes, but much more commonly in females than males. There is rarely any family history of psychoneuroses or psychoses. The anorexia is in most cases at first the visceral expression of some emotional disturbance, often an unhappy love affair. Sometimes the diet is voluntarily reduced with the object of overcoming a real or imaginary tendency to get fat, or on account of some fanciful ideas concerning the effect of food in stimulating sexual activity. Whatever the origin of the condition may be, the restriction of food results in the gradual disappearance of the appetite until the patient loses all desire for food. After the anorexia has continued for some time its origin, which is never recognised by the patient without explanation, recedes into the background, and it often remains after the psychological difficulties which gave rise to it have disappeared.

The constant presence of amenorrhœa has led to the idea that the condition is the result of endocrine disorder. But there is no good evidence for this theory, and complete recovery always follows simple psychotherapy without accessory treatment of any kind. There is also no justification for comparison with Simmonds's disease, a very rare condition, caused by degeneration of the anterior lobe of the pituitary gland; this is not necessarily associated with either anorexia or emaciation, and is uninfluenced by psychotherapy.

Symptoms.—The patient has a great repugnance for every kind of food, and as even small quantities have to be forced down, they give rise to a sense of complete repletion and distension and sometimes nausea. He may learn to vomit at will, and as he realises that he can overcome his discomfort by this means, it may occur after every meal. The small intake of food leads to increasingly severe constipation, and the aperients used for its treatment increase the abdominal discomfort.

The patient rapidly loses weight and in time becomes extremely emaciated, almost all the subcutaneous fat disappearing. At first physical and mental activity are unabated, the restless energy and absence of fatigue being in striking contrast with the wasted appearance of the patient, but in the later stages the patient becomes weak and lethargic, and finally may lie in bed unable to move a limb or raise his head. In girls amenorrhœa is a constant symptom; it develops at an early stage and persists for many months after recovery is complete in all other respects. It is probably of psychical origin and not a result of malnutrition, as it develops at an early stage and may persist long after the patient has returned to a normal diet. An abnormal growth of hair is a common symptom; this is a direct result of malnutrition, as it is constantly observed in times of famine.

The pulse and temperature are normal. The X-rays show no abnormality in the alimentary tract, the constipation being due solely to the insufficient quantity of food residue, and gastric secretion is unaffected. The extremities and the nose and ears are cold and blue, the skin dry and scaly. The urine is normal.

If proper treatment is not instituted, death may result from inanition, extreme atrophy without any organic visceral lesion being found *post mortem*.

Treatment.—Except in the earliest stages, it is essential to remove the patient from his home surroundings and to allow only infrequent visits from his relations. The nature of the symptoms is explained to him, and he is made to understand that he can recover and return to his home and to a normally active life only when, as a result of eating a proper quantity of ordinary food, his weight and strength have returned, and that though this may entail some discomfort at first, his appetite is certain to return when more food is taken. It is essential to be present during the first meals after treatment is begun, and to be prepared to spend a very long time arguing over every mouthful until the meal is at last finished. As resistance almost invariably breaks down under these conditions, the task of supervising subsequent meals can be left to a good nurse, who must at first never leave the patient, as otherwise food is likely to be hidden or thrown away. The patient should from the first day of treatment be given a full diet without restrictions of any kind, and should be induced to eat everything he is given.

With tact, explanation and persuasion this is always possible. The psychological origin of the trouble should not be discussed until the patient has greatly improved; even then such discussion is not always necessary, and it is rare for anything more than simple psychological explanation without any deep analysis to be required. Special diets, organotherapy, including gonadotrophic and pituitary hormones and the use of insulin to stimulate the appetite, and the administration of vitamins are of no use in the treatment of anorexia nervosa.

NAUSEA

Nausea most commonly precedes vomiting and is relieved when the stomach is empty. When associated with headache it is generally a result of migraine. It may occur as an independent symptom in chronic achlorhydric gastritis, chronic cholecystitis and in the earliest stage of carcinoma of the stomach. It is sometimes the most prominent symptom in early tuberculosis and at the commencement of pregnancy. It may occur in nephritis and infections of the urinary tract, and in men it may result from prostatic disease; in these conditions it is generally an indication of the onset of uræmia, of which it may be the first symptom. All these possibilities should be excluded before regarding it as of nervous origin, but there is no doubt that it is occasionally an hysterical symptom and due to the perpetuation by auto-suggestion of nausea which originally resulted from the emotion of disgust, although the actual exciting incident may have been forgotten.

Nausea may be constant or periodic. It may be specially associated with the consumption of fatty food or less frequently of meat, but it is often quite independent of the kind or nature of the food taken. The patient may wake up with severe nausea, which makes it difficult for him to eat any breakfast. He often thinks it is due to some disease of the stomach, and he consequently reduces the amount of food he takes; severe loss of weight may result. Nausea is often increased by emotional disturbances and may be less troublesome when the mind is fully occupied.

GASTRIC FLATULENCE: AEROPHAGY

Flatulence, or the presence of excess of gas, may occur simultaneously in the stomach and the intestine, but in many cases it is confined to the stomach or to some part of the intestines.

Ætiology.—Gastric flatulence may be caused by (*a*) excessive production of gas by fermentation or putrefaction; (*b*) the introduction of excess of air by aerophagy; and (*c*) deficient elimination.

(*a*) Achlorhydria may be associated with the formation of a small quantity of gas by bacterial activity, but this is very rarely sufficient to cause discomfort. In pyloric carcinoma, achlorhydria is associated with severe gastric stasis, and a considerable excess of foul gas may be produced.

(*b*) Aerophagy is the commonest cause of flatulence. It is often associated with functional dyspepsia, but it is equally common in organic diseases,

especially cholecystitis and less frequently gastric and duodenal ulcer, and the pain in angina pectoris frequently causes aerophagy. The patient feels discomfort in the stomach, which he thinks is due to "wind," and which he imagines he can "disperse" by eructation; as there is really no excess of gas present, the attempt proves unsuccessful and results in the swallowing of air. After half a dozen or more attempts have been made without success, air being swallowed on each occasion, the stomach becomes distended with air, which is noisily expelled. The excessive salivation, which often occurs in gastric disorders associated with hyperchlorhydria, and in septic conditions of the mouth and naso-pharynx, also leads to flatulence, as air is swallowed with each mouthful of saliva. The severest cases of aerophagy occur independently of dyspepsia in intensely neurotic women; the symptom is then hysterical. A little saliva with a large quantity of air is swallowed until the stomach is distended, when it is noisily pumped backwards and forwards between the stomach and œsophagus by spasmodic movements of the diaphragm, and is periodically expelled with a loud report.

(*c*) Deficient elimination of gas occurs when absorption is diminished owing to chronic gastritis with much secretion of mucus or to the obstruction of the portal circulation which occurs in cirrhosis of the liver and heart failure; swallowed air and the gases produced by fermentation are insufficiently absorbed and severe flatulence results.

Symptoms.—Gastric flatulence gives rise to a sensation of fullness in the epigastrium, which may extend under the left costal margin. The accumulation of gas in the stomach pushes up the diaphragm; this may cause palpitation and attacks of dyspnœa in individuals who are predisposed by such conditions as asthma and cardiac weakness. Flatulence may also be the immediate cause of an attack of true angina pectoris, though more frequently the angina is the cause of the aerophagy.

In rare cases a valvular mechanism is set up at the cardia, which does not impede swallowing but prevents the passage of gas in the opposite direction. This *aërogastrie bloquée* may result from spasm of the lower end of the œsophagus associated with an œsophageal ulcer, or from a kink caused by the dislocation of the stomach from the pressure of a distended splenic flexure in intestinal carbohydrate flatulence or a distended pelvic colon in megacolon. An enormous quantity of gas may collect in the stomach, the distension of which causes great pain, which is relieved by lying down, when the gas passes on into the duodenum, or instantaneously by the passage of a stomach tube.

Diagnosis.—When a patient complains of "flatulence," it is first necessary to ascertain whether excess of gas is really present. This can be done most readily and accurately by means of X-rays, as it is often difficult to distinguish by percussion whether an accumulation of gas is in the stomach or in the splenic flexure of the colon.

Pseudo-flatulence is generally due to the patient misinterpreting the sensation of fullness which is caused by the increased intragastric pressure produced by sudden distension of the stomach, especially if it is of the short, high form, with excess of food and drink which have been too rapidly consumed. There is no abdominal swelling or increase in gastric resonance, and the patient is unable to bring up any gas, but the condition is often complicated by aerophagy. The eructation of swallowed air may relieve the discom-

fort which prompted the aerophagy; this is probably due to the increased intragastric pressure overcoming the resistance of a pyloric sphincter closed as a result of achalasia or spasm at the same moment as the resistance at the cardia is overcome.

Excess of gas in the splenic flexure in intestinal carbohydrate dyspepsia and in the pelvic colon in megacolon often gives rise to a feeling of fullness in the left hypochondrium, which is mistaken by the patient for gastric flatulence and may lead to aerophagy.

Pseudo-flatulence may also be caused by *hysterical spasm of the diaphragm*. This may occur as an independent condition or as a complication of some organic disorder, such as gastric ulcer or colitis, or after a blow on the abdomen. It is also the cause of the abdominal distension in *pseudocyesis*, in which pregnancy is simulated. The spasm may be continuous and last for weeks or months. More frequently it occurs in attacks; a sensation of great distension is experienced and the abdomen becomes so protuberant that the clothes have to be loosened. The "distension" disappears as suddenly as it comes without eructation or passage of flatus. It often leads to a mistaken diagnosis of intestinal obstruction, and laparotomies have been performed in spite of the fact that the distension disappears under an anæsthetic. The lower ribs are drawn in as a result of the pull of the contracted diaphragm, and firm manipulation of the abdomen causes the abdomen to become flat and the diaphragm to rise. The absence of excess of gas in the stomach and intestines can be recognised with the X-rays, which also show the very low position of the diaphragm and the shallow respiratory movements. The patient should be taught to breathe properly with his diaphragm, but improvement is often very slow.

The gas expelled in aerophagy is odourless; when caused by purtefaction in pyloric obstruction it is offensive, and this is occasionally the first symptom of a growth, though it may also occur in non-malignant obstruction. Aerophagy is probably present if eructation is frequently repeated; the diagnosis is certain if it occurs several times in rapid succession, as fermentation cannot give rise to such a large quantity of gas. Eructation occurring before breakfast in the absence of pyloric obstruction is always due to aerophagy, as there is nothing in the stomach from which gas could be produced. The diagnosis can be confirmed by means of the X-rays, with which it is easy to watch the whole process of aerophagy.

Treatment.—The treatment of flatulence due to excessive fermentation consists in removing the cause. When flatulence is due to aerophagy, it is generally only necessary to explain to the patient the cause of his trouble in order to cure him. He should be told not to eructate, however much he may desire to do so. If he finds it very difficult to restrain himself, he should open his mouth or clench his teeth upon a cork, whenever the desire is very strong, as it is then difficult to swallow air, though any excess of gas in the stomach can be expelled. When aerophagy is secondary to dyspepsia, this requires appropriate treatment. Momentary relief, sufficient to help the patient to forego eructation, can generally be obtained by sipping hot water or chloroform water, or by taking a few drops of a carminative, such as oil of cinnamon or peppermint on a lump of sugar, but the use of spirits for this purpose should be prohibited.

NERVOUS DYSPEPSIA

Ætiology.—Most neurasthenic patients suffer from indigestion, partly as a result of their abnormally irritable nervous system and partly as a result of chronic toxæmia, depressing emotions, mental and physical overwork, and the other factors concerned in the production of neurasthenia, as these tend in themselves to inhibit the motor and secretory functions of the stomach.

Anxiety neuroses are often accompanied by visceral symptoms. The nature of the latter depends upon the patient's past history and physical make-up. If he has suffered from indigestion in the past or if he has an organ inferiority in the form of the hypersthenic or hyposthenic gastric diathesis, nervous dyspepsia is likely to develop.

Symptoms.—The gastric symptoms in nervous dyspepsia are characterised by their extreme irregularity, the patient feeling very ill one day and comparatively well the next without any obvious reason for the change. The most constant complaint is of vague abdominal discomfort, which rarely amounts to actual pain. It is generally worst in the morning and improves towards evening, but in some cases the symptoms increase when the patient becomes more fatigued towards evening. The discomfort is aggravated by meals, a sensation of fullness being felt as soon as a small quantity of food has been eaten, but it may be present to a less extent before breakfast. It has little relation to the amount or the kind of food, differing in this way from the discomfort of organic gastric disorders. It is increased by worry and excitement, while some new interest, whether it be a change of surroundings, a game, a conversation, a new medicine or a new doctor, leads to its temporary disappearance. Nausea sometimes occurs, but vomiting is unusual. Many patients complain of flatulence, which is generally due to aerophagy, but may be nothing more than the result of misinterpreting the sensation of fullness, no excess of gas being present (see p. 574). The appetite is always diminished, though it varies considerably from day to day. As insufficient food is taken, the nervous system becomes more depressed; this reacts again on the digestion, a vicious circle being produced.

Physical and radiological examination of the stomach very rarely shows any abnormality. Evacuation of the gastric contents may be slightly delayed owing to periods of inertia alternating with periods of normal peristalsis. The secretion of gastric juice may be temporarily diminished. If nervous dyspepsia develops in a patient with the hypersthenic gastric diathesis, the symptoms are likely to simulate those of duodenal ulcer. Constipation is almost always present. The abdominal muscles may be tense so that examination is difficult, but there is never any great degree of tenderness, and what is present is diffuse and variable in position rather than localised and constant. In other cases the abdominal muscles are weak, and symptoms resulting from this may be added to those resulting from the neurasthenia or anxiety neurosis.

The gastric symptoms are always associated with other nervous symptoms, such as headache, backache and insomnia, and the anorexia leads to progressive loss of weight and strength. The abdominal discomfort may be accompanied by flushing of the face, palpitation and coldness of the ex-

tremities. The patient is generally depressed and pessimistic; he pays great attention to all his bodily functions, constantly looking at his tongue taking his temperature and examining his stools. His account of his symptoms is full of details, and he often has some theory to account for them, believing himself to be suffering from some mythical disorder such as acidity, a dropped stomach or colon, mucous colitis or intestinal auto-intoxication, and not infrequently he fears he has cancer. He may seek advice for dyspepsia on its own account or because he thinks that it is the cause of his purely nervous symptoms.

Treatment.—The patient's confidence can be gained only after a very thorough examination. He can then be told that he has no organic disease, and that with perseverance he will get well. The general neurasthenic condition first requires attention: for this mental and physical rest, followed by graduated exercise, and sufficient food to overcome the inanition are the chief indications. Congenial surroundings, cheerful companions and appetising food are of great importance, and consequently strict isolation is not required. For the anxiety symptoms psychotherapy, preferably of a simple kind, is essential. The dyspepsia itself generally requires no special treatment, as it disappears with reassurance that there is no organic abdominal disorder and with successful treatment of the underlying nervous condition.

HYSTERICAL GASTRIC SYMPTOMS

When symptoms such as vomiting, anorexia, nausea and abdominal pain have been caused by emotional disturbance or by gastritis, gastric ulcer, appendicitis or other organic cause, they may continue or recur as the result of suggestion after the original cause has disappeared. They are then hysterical symptoms. Hysterical digestive symptoms are always curable by psychotherapy. In severe cases it is essential to remove the patient from his home surroundings. In the majority of cases explanation, persuasion and re-education effect a cure without recourse either to gross suggestion or to elaborate psycho-analysis.

Hysterical Vomiting

Hysterical vomiting occurs during or immediately after meals. It is effortless and generally unaccompanied by nausea, so that a patient may vomit meat and vegetables, and immediately afterwards be ready to eat a sweet which he retains without difficulty. The stomach is generally only partially emptied, so that nutrition is preserved, but in rare cases nothing is retained, and severe emaciation, together with the changes in the urine which follow starvation and have erroneously been ascribed to toxæmia, results. The diet has often no effect, vomiting being as frequent with milk alone as with a full diet.

When the vomiting of early pregnancy, which is probably reflex in origin, occurs after every meal instead of only in the morning, and when it persists after the eighth week, it is often called the *pernicious vomiting of pregnancy*. It has generally been regarded as toxic on account of certain changes in the urine and associated symptoms. I am convinced, however,

that it is always hysterical, as in my experience it can invariably be cured by psychotherapy with great rapidity. The changes in the urine—excess of organic acids and a rise in the ammonia index (the proportion of nitrogen present as ammonia compared with that as urea) are entirely secondary to the starvation and dehydration which result from persistent vomiting. However marked these changes may become—and I have known the ammonia-index rise from the normal 5 to 28—and however severe the so-called toxic symptoms may be, such as a dry, black tongue and a pulse as rapid as 160, they all disappear within 24 or 48 hours with psychotherapy in the form of explanation and persuasion without either suggestion or drug treatment. The condition must of course be distinguished from the vomiting, which begins in the later stages of pregnancy and is only one symptom of some obviously toxic condition, such as eclampsia or acute necrosis of the liver.

Hysterical vomiting was a common sequel of the acute gastritis caused in the War of 1914–1918 by gassing, when some of the irritant gas was dissolved in saliva and swallowed. The vomiting persisted without any other symptoms after the gastritis had disappeared. It was always rapidly cured by simple psychotherapy.

Treatment.—A patient with hysterical vomiting should be kept in bed and isolated. After the exciting cause has been discovered and the reason for the continuation of the vomiting has been explained to him in language suited to his intelligence, he should be made to realise that now that the primary cause is no longer operative, his stomach has simply developed a bad habit, which it must be educated to give up. Full diet should be given from the onset. It is always desirable to be present whilst the patient takes his first meal under the new regime in order to encourage him to suppress his desire to vomit. After one meal has been eaten without vomiting complete recovery is generally very rapid.

HÆMATEMESIS AND MELÆNA

Ætiology.—Hæmatemesis results most frequently from a chronic ulcer of the stomach, duodenum or œsophagus, or of the jejunum after gastro-jejunostomy. It occurs generally in smaller quantities, in cancer of the stomach. The term *gastrostaxis* was at one time applied to the hæmorrhage which was supposed to occur in the absence of any organic lesion; but gastroscopy and examination of fresh specimens removed at operation have proved that very small rapidly healing and often multiple erosions or acute ulcers, which readily escape detection both on external examination during an operation and at autopsy, are present in such cases in association with gastritis. Hæmorrhage may occur in susceptible people from areas of the mucous membrane which become congested and hæmorrhagic on contact with fragments of aspirin. There is no evidence that vicarious menstruation from the stomach ever occurs, although hæmatemesis is rather more common during menstruation than in the intervals. The varicose veins which develop in the œsophagus in cirrhosis of the liver may bleed, and hæmorrhage may also occur from the congested gastric mucous membrane in cirrhosis and heart failure. Bleeding from the stomach is a common symptom of splenic anæmia, even in the early stages when the liver is still comparatively healthy.

It may also occur in the hæmorrhagic diathesis, which is in most cases associated with a reduction in the number of blood platelets and delayed bleeding time (thrombocytopenic purpura); it is then generally preceded and accompanied by purpura and often by hæmorrhage from the nose, kidneys or other organs, but in some cases it may be the sole manifestation of the condition. In rare cases hæmatemesis is caused by bleeding from multiple telangiectases of the gastric mucous membrane in patients with familial telangiectasia; it is then almost invariably associated with epistaxis. Finally, blood from the naso-pharynx, mouth, œsophagus and lungs may be swallowed and vomited.

Diagnosis.—Direct examination of the nose, gums and pharynx excludes the possibility of the blood coming from these sources. Hæmatemesis may be distinguished from hæmoptysis by the fact that in the former the blood is generally dark, partly coagulated and mixed with more or less food, whereas in the latter it is bright red, frothy and uncloted; in the former the symptoms may point to gastric disease, in the latter to disease of the lungs or the heart; melæna is present in most cases and occult blood in all cases after hæmatemesis, and the hæmorrhage is not often repeated, whereas in hæmoptysis the stools contain no blood, and the patient generally continues to expectorate blood-tinged sputum for several days. In chronic ulcer and carcinoma of the stomach a history of other gastric symptoms can almost always be obtained, though in chronic ulcer they may be very mild in character and of short duration. In cirrhosis of the liver, symptoms of alcoholic gastritis are often present, and the liver is generally hard and enlarged. When hæmatemesis occurs without other symptoms, gastritis with an acute ulcer or erosion is generally present, if splenic anæmia can be excluded by the absence of splenomegaly and leucopenia, the hæmorrhagic diathesis by absence of purpura or bleeding from other mucous membranes and the presence of a normal number of blood platelets and normal bleeding time, and familial telangiectasia by absence of epistaxis and telangiectasia of the face. The possibility of an idiosyncrasy to aspirin should always be considered when a patient is in the habit of taking the drug frequently, especially if he swallows tablets whole and apart from meals.

Prognosis.—The mortality among patients with hæmorrhage from an ulcer is about 1·5 per cent. in general practice. As the incidence of hæmorrhage in cases of gastric, duodenal and anastomotic ulcer taken together is about 25 per cent., the mortality from hæmorrhage in all cases of ulcer, whether they have previously bled or not, is about 0·4 per cent. The mortality of cases of ulcer admitted into Guy's Hospital under my care on account of hæmorrhage is 4·8 per cent.; the mortality from hæmorrhage in patients with a history of hæmorrhage from ulcer or admitted for ulcer is under 2·5 per cent., and the mortality from hæmorrhage of all cases of ulcer, including those which have never bled, is about 1 per cent.

Treatment.—The patient should be kept completely at rest without transportation to a nursing home or hospital. He should be kept in the supine position, and should not leave his bed even to micturate or defæcate until there has been no hæmorrhage for 48 hours. In order to keep him completely at rest and to allay anxiety it is generally advisable to inject morphine. Nothing should be given by mouth for 24 or 48 hours; small quantities of dilute citrated milk may then be drunk and the quantity rapidly increased so that within a while the patient is on the ordinary strict ulcer diet (p. 594)

with 5 oz. hourly feeds. The so-called Meulengracht diet has nothing to recommend it for use in England. The improved results following immediate feeding recorded by Meulengracht were due to the prolonged starvation and deprivation of fluids formerly practised in Denmark. In England death is almost always a direct result of hæmorrhage from a large hole in a sclerotic artery and not from starvation or dehydration. Normal saline solution, ½ to ¾ pint, should be given four hourly by rectum until sufficient fluid is taken by mouth. Constipation requires no treatment, as the bowels generally open spontaneously on the third day after one of the saline injections.

If the hæmoglobin falls below 30 Oer cent., the patient should be transfused. Not more than 10 oz. of blood should be given and the transfusion should not be repeated unless the hæmorrhage recurs. Transfusion is required to prevent a patient from dying from anæmia; it is not required for the restoration of the blood to the normal level, as an average gain of 1 or 2 per cent. of hæmoglobin per diem occurs when 30 grains of iron and ammonium citrate, which is always well tolerated, are given three times a day. Clotting is most likely to occur when the circulation is at a low ebb with the blood pressure low and the patient collapsed. A rapid rise in blood pressure may lead to recurrence of hæmorrhage, which would not take place if the rise in hæmoglobin is as gradual as it is with the administration of iron. If the hæmorrhage is gastric and not duodenal in origin and continues to a dangerous extent, a stomach tube attached to Senoran's evacuator should be passed; the stomach is emptied and then washed with successive half-pints of iced water until the latter is no longer tinged with blood, when 60 minims of solution of adrenaline hydrochloride (1 in 1000) may be left in the stomach.

For surgical treatment *vide* p. 596.

ORGANIC DISEASES OF THE STOMACH

ACUTE GASTRITIS

(*a*) Acute Catarrhal Gastritis

Ætiology.—Acute catarrhal gastritis is caused by severe irritation of the mucous membrane of the stomach. A large indigestible meal and excess of alcohol are common causes, especially if the patient is already suffering from chronic gastritis. In many cases the irritant is a toxic product of bacterial activity in food, several individuals being often simultaneously affected. The symptoms of gastric influenza are due to acute gastritis produced by the influenza toxin, and the toxins of scarlet fever, septicæmia and other acute infections and those of uræmia may also be excreted into the stomach and give rise to gastritis. The swallowing of saliva in which irritant gases were dissolved often resulted in the production of acute gastritis during the War of 1914–1918, but the symptoms were generally overshadowed by the more serious pulmonary symptoms; in some cases the occurrence of hæmatemesis indicated the severity of the lesion. Recovery was always rapid, and when vomiting persisted it was always hysterical.

Symptoms.—The symptoms start acutely soon after the entrance of the irritant into the stomach, but they may be postponed for several hours when the attack is due to a toxin produced by bacterial activity within the stomach. A sensation of fullness and discomfort is felt in the epigastrium; heartburn is common, and in severe cases there is acute pain. Tenderness is diffuse and generally only moderate in degree, but in serious cases it may be extreme. The abdomen may be distended. The appetite is completely lost, but thirst is excessive. The tongue is covered with a thick dirty fur, and there is an unpleasant bitter taste in the mouth. The patient constantly eructates, and the gas brought up may be foul-smelling. Vomiting, preceded by nausea, almost always occurs, and gives more or less relief to the discomfort and pain. The food eaten at the previous meal, mixed with mucus but with little or no gastric juice, is first rejected; subsequently mucus with saliva, which is generally secreted in excess, bile and occasionally small quantities of blood are vomited. Severe constipation is present unless the irritant also acts upon the bowels and causes diarrhœa. The vomited matter contains no free hydrochloric acid, but is generally acid in reaction owing to the presence of lactic, butyric and other fatty acids; the saliva and mucus present may, however, give it an alkaline reaction. Microscopically, leucocytes, epithelial cells, and sometimes blood are found.

The patient is pale and prostrated and complains of headache. These symptoms are most marked in infective cases, when the patient may also be drowsy and even delirious. The temperature is generally slightly raised, but it may be high, especially in children, and the pulse is rapid. Leucocytosis is common, even in the absence of pyrexia. The urine is concentrated and may contain a trace of albumin. Herpes labialis is sometimes present. Contrary to what might be expected, a test-meal given 12 to 24 hours after the onset shows that the initial paralysis is followed by increased motor activity and the acidity tends to be high rather than low, though it subsequently falls, as a second test-meal given a week later shows that hypochlorhydria gives place to achlorhydria and an average acidity to hypochlorhydria. Mucus, leucocytes and epithelial cells are present in excess.

Diagnosis.—In severe pyrexial cases the symptoms may simulate the onset of an acute infection, such as typhoid fever, but the rapid improvement soon makes the diagnosis clear. I have seen cases in which the pain, tenderness and rigidity were so severe that considerable doubt was felt at first whether a gastric ulcer might not have perforated.

Prognosis.—Recovery generally takes place within 24 or 48 hours, but in toxic and infective cases the acute symptoms may persist for several days, at the end of which they may suddenly disappear. The condition often passes into chronic gastritis, which may remain completely latent, though the stomach is often abnormally irritable for a considerable time.

Treatment.—The patient should be kept warm in bed with hot applications to the abdomen. If the stomach is not spontaneously emptied, vomiting should be induced by drinking half a pint of warm water, in which 60 grains of sodium bicarbonate has been dissolved; when this fails, the stomach should be washed out.

Chloroform water often relieves the nausea. Castor oil, followed, if necessary, by a saline aperient, should be administered if there is constipa-

tion. No other drugs need be given except in the rare cases in which very severe pain persists after the stomach is empty, when an injection of morphine may be required. Nothing but water, which may be flavoured with tea, should be taken until all the acute symptoms have disappeared; sweetened arrowroot made with water may then be given, and, as the appetite returns and the tongue cleans, dilute citrated milk, farinaceous food, eggs, and lastly, fish, chicken and meat can be added to the diet. A test-meal should be given when the patient is convalescent, as if chronic gastritis, with or without achlorhydria, has developed, appropriate treatment may prevent the onset of various complications at a later date.

(*b*) Acute Suppurative Gastritis

Ætiology.—This very rare disease is due to the invasion by streptococci or less frequently pneumococci, staphylococci or *B. coli*, of the submucous tissue through a carcinomatous ulcer, or still more rarely through a chronic ulcer or the wound left after an operation on the stomach. In exceptional cases the point of invasion cannot be recognised. The condition may also occur in pyæmia, anthrax and smallpox.

Symptoms.—Epigastric pain and tenderness are severe. Vomiting is always present. The vomitus may contain pus owing to the rupture of a localised abscess into the lumen of the stomach. Peritonitis generally supervenes in the course of 2 or 3 days. The general symptoms present are those common to severe infections.

Prognosis.—A local submucous abscess may burst inwards and spontaneous recovery follows, but more commonly it ruptures outwards, producing general peritonitis. Diffuse suppurative gastritis always ends in peritonitis.

Treatment.—In very rare cases a localised abscess has been treated successfully by operation.

(*c*) Acute Phlegmonous Gastritis

Ætiology.—Phlegmonous gastritis results from the ingestion of irritant poisons, such as concentrated acids and alkalis, arsenic and antimony.

Symptoms.—The local symptoms are similar to those of acute suppurative gastritis, except that the vomited matter frequently contains blood and sometimes sloughs. The patient is collapsed and may become comatose, the symptoms depending upon the nature of the poison.

Prognosis.—Death frequently occurs from shock, general peritonitis or the effect of the poison on other parts of the body. If the patient recovers, achylia gastrica is almost always present as a result of atrophy of the mucous membrane, and pyloric obstruction frequently develops. A patient of mine vomited a complete cast of the pyloric half of his stomach a month after swallowing spirits of salts; recovery followed gastro-jejunostomy performed for the obstruction which ensued.

Treatment.—An attempt should be made to dilute and neutralise the poison. When this is impossible the stomach should be washed out. Morphine should be injected to relieve pain and to keep the patient quiet.

CHRONIC GASTRITIS

Ætiology. — Chronic gastritis is a very common condition. Its ætiology and pathogenesis have been discussed in the Introduction (p. 558).

Catarrh of the gastric mucous membrane is a frequent sequel of the congestion caused by diseases of the heart, lungs and liver.

Symptoms.—Chronic gastritis, especially the atrophic form, is often completely latent. When symptoms occur, their nature depends upon whether the condition has developed in an individual with the hypersthenic gastric constitution—acid gastritis, or in one with the hyposthenic gastric constitution—achlorhydric gastritis.

(*a*) *Acid gastritis.*—Acid gastritis rarely gives rise to symptoms unless it is complicated by acute or chronic ulcer (*q.v.*). In the exceptional cases in which symptoms occur in the absence of a chronic ulcer they are indistinguishable from those of duodenal ulcer, and a diagnosis can be made only when repeated X-ray examinations show that there is no constant gastric or duodenal deformity in spite of the presence of typical symptoms, tenderness and rigidity associated with hyperchlorhydria, and sometimes occult blood in the stools. Hæmatemesis may occur from an acute ulcer or erosion, which gives no radiological signs of its presence, but which can be clearly demonstrated by gastroscopy, which generally shows the presence of the hypertrophic form of gastritis. As the hypersthenic stomach is incapable of secreting much mucus, the absence of mucus from the fractions of a test-meal is no evidence against the presence of gastritis.

The treatment is that of ulcer, but the period of bed and strict dieting need not be prolonged more than a week unless occult blood continues to be present in the stools. It is, however, essential that the patient should permanently follow the "post-ulcer regime" (p. 595), as otherwise an ulcer will almost certainly develop sooner or later.

(*b*) *Achlorhydric gastritis.*—In the Introduction it was pointed out that achlorhydria is almost certain to develop if chronic gastritis occurs in a patient with the hyposthenic gastric constitution. The symptoms are mainly due to the achlorhydria and the complications to which it gives rise, so that it is unusual for the condition to be discovered when there is still free acid in any fraction of the test-meal.

The most common gastric symptom is nausea, although it is only present in a small percentage of cases. It occurs especially in the early morning, but may last throughout the day. When severe it leads to anorexia, which may also be present in the absence of nausea. The association is particularly evident in alcoholic gastritis, in which morning nausea with inability to eat any breakfast in spite of a good appetite for lunch and dinner is a characteristic symptom.

Pain never occurs in uncomplicated achlorhydric gastritis, but slight epigastric discomfort, generally described as fullness, pressure or heaviness, is not uncommon. It follows immediately after meals, and may last several hours in the small group of cases in which evacuation is slow. It is often partially relieved by belching, but frequent attempts to eructate may result in aerophagy. In spite of the presence of achlorhydria heartburn and sour

regurgitation, which are relieved by sodium bicarbonate, may occur. Tenderness is slight and ill-defined, and there is no rigidity.

Vomiting occurs if nausea is severe, or if the epigastric discomfort is unusually prolonged. It is often to a large extent voluntary, the patient having discovered that it gives relief. The vomited material generally consists of undigested food mixed with mucus and often with bile, but the morning vomit of alcoholics is an alkaline, mucous fluid, composed of swallowed saliva and secretion from the inflamed pharynx and œsophagus.

Constipation is generally present, but in one group of cases chronic or intermittent attacks of diarrhœa occur, and may persist for many years with little or no gastric symptoms which might suggest its gastrogenous origin (*vide* p. 623).

The tongue is generally clean, but in alcoholic gastritis it is often furred and the patient complains of an unpleasant taste in his mouth. When achlorhydric gastritis is associated with anæmia, whether simple or Addisonian, atrophy of the filiform papillæ is often present, generally accompanied by recurrent attacks of subacute glossitis, in which the patient complains of soreness of the tongue.

The size, tone and rate of evacuation of the stomach are generally normal, but evacuation is unusually rapid and the stomach short and high in some cases of complete achylia. In the achlorhydria following the gastritis of an acute infection it may be slow owing to the rapid exhaustion of peristalsis, the X-rays showing periods of complete inertia alternating with periods of normal activity.

The test-meal gives some indication of the severity of the gastritis. In early cases a little free acid may be present in some of the fractions, but more commonly by the time the patient comes under observation achlorhydria is complete. In most cases mucus is present in the resting juice and in each fraction, and the curve of total acidity remains moderately high above the base line. In advanced cases, in which atrophy of the mucous membrane has occurred and involved the superficial mucus-secreting cells as well as the tubules, mucus is absent and the total acidity is much reduced. So long as mucus is present, treatment is likely to result in recovery of the power of secreting free acid, but this is very rare in the absence of mucus. In the former case, but not in the latter, an injection of histamine when fasting or at the end of the test-meal is generally followed by the secretion of free acid. It is, however, unnecessary to perform this test, as histamine never succeeds in producing free acid when treatment with lavage fails, and treatment is occasionally followed by restoration of secretion in histamine-refractory achlorhydria.

Treatment.—All possible causes of gastritis should be removed as far as possible. The teeth should be put into perfect condition and artificial ones supplied when necessary. Septic tonsils should be enucleated, and nasal infections thoroughly treated. If the tongue is furred it should be frequently scraped, and sufficient dry food should be given to promote an adequate secretion of saliva. The food should be thoroughly chewed and eaten at regular times, the last meal at least two hours before going to bed. The patient should rest for half an hour after meals, and, if he is tired, for half an hour before meals.

Alcohol should be entirely prohibited, and smoking limited to a few

cigarettes with plugs of wool in the mouthpiece after meals. Tea must be weak and freshly brewed, and coffee (unless caffeine-free) only drunk if mixed with at least an equal quantity of milk. Meat should be allowed at only one meal a day and should be very tender. Game and ripe cheese, coarse bread substitutes and oatmeal, skins and pips of fruit, salads, pickles and green vegetables, except as purées, should be prohibited. A purée of spinach is particularly useful, as it contains a histamine-like substance which is a powerful stimulant of gastric secretion, even when taken by mouth. In severe cases, especially if the stools contain occult blood, it is best to start with a diet similar to that required for the treatment of ulcer.

If any mucus is present in the test-meal, the stomach should be washed out every morning with dilute hydrogen peroxide, beginning with 60 minims and increasing gradually to 240 minims to the pint. The nascent oxygen given off dislodges the mucus from the surface of the mucous membrane, and at the same time acts as an antiseptic and perhaps stimulates the secretion of gastric juice. The patient should learn to wash his own stomach out so that the lavage can be continued every day until no mucus is washed away; it can then be given every other day, then twice a week, and finally once a week for some months. The test-meal should be repeated after the mucus has disappeared; the secretion of acid returns in 80 per cent. of cases, often within a fortnight, but occasionally only after 4 to 6 weeks. If the original test-meal showed that no mucus was present, it is rarely worth while trying treatment by lavage, as the atrophy of the gastric mucous membrane is generally too far advanced for the secretion of acid to return.

In old and debilitated patients, for whom lavage seems too strenuous a treatment, a teaspoonful of sodium bicarbonate in a glass of soda water, drunk whilst fasting first thing in the morning, has a similar though less powerful action.

If treatment by lavage does not result in the return of secretion, and in all cases in which mucus is absent from the original test-meal, hydrochloric acid should be given. From 60 to 120 minims in 5 to 10 oz. of water to which sugar and the pulp and juice of an orange have been added, are drunk before breakfast and as a beverage with lunch and dinner; 5 grains of pepsin should be added to the two latter doses.

In hypertrophic gastritis, in which free hydrochloric acid is still secreted, lavage with silver nitrate solution is the most satisfactory treatment. The stomach is washed out every morning with successive quantities of a 0·05 per cent. solution until no more white precipitate of silver chloride is evacuated; when three clear washings have been obtained a final wash should be made with plain water. If the lavage causes no pain the strength of the solution should be increased successively to 0·1, 0·15 and 0·2 per cent.

The bowels should be kept regular by taking honey, fruit jelly, stewed fruit, from which pips and skins have been separated, and green vegetable purées. If necessary, liquid paraffin can be given, but irritating aperients should be avoided.

GASTRIC AND DUODENAL ULCER

Ætiology.—A chronic gastric ulcer was found by Stewart in 2·2 per cent. and a chronic duodenal ulcer in 3·8 per cent. of 4000 consecutive autopsies.

The scars of healed ulcers were found in the stomach in 2·3 per cent. and in the duodenum in 3 per cent. of the series. Chronic ulcers or scars were found in the stomach and duodenum of the same individual in 0·5 per cent. Thus a chronic ulcer, healed or unhealed, was found in 9·5 per cent. of post-mortems, and it may therefore be assumed that about 10 per cent. of all individuals suffer at some time in their lives from a chronic gastric or duodenal ulcer. Duodenal ulcers occur between three and four times as frequently as gastric ulcers in better-class practice, but gastric and duodenal ulcers are about equally common in hospital patients.

Chronic gastric ulcer occurs with equal frequency in males and females, but duodenal ulcer is about four times more common in males than females.

Chronic ulcer is rarely diagnosed in children, but the symptoms date from the age of 14 to 20 in about 12 per cent. of cases recognised later in life. It is rare for an ulcer to develop after the age of 50 in women, but in men the first symptoms not infrequently appear between 50 and 60 and occasionally even later. The average age of onset of gastric ulcer in women is 26 and in men 45 ; that of duodenal ulcer is 38 in both sexes.

Chronic ulcer frequently occurs in several members of a family in one or more generation. The ulcer is generally either gastric or duodenal in all the affected members. In familial cases the symptoms tend to begin at an earlier age than usual, and there is a great tendency for anastomotic ulcers to form after operation. There is also a special tendency in some families for the ulcers to be complicated by hæmorrhage.

Pathogenesis.—The pathogenesis of chronic ulcer has already been discussed in the Introduction, and only certain points require further consideration here. The peculiar type of ulcer found in the stomach and duodenal bulb occurs nowhere else except in the part of the jejunum immediately distal to the anastomosis after gastro-jejunostomy and partial gastrectomy, in the lower end of the œsophagus when relaxation of the cardiac sphincter allows gastric juice ro regurgitate, and also in association with heterotopic gastric mucosa in the lower extremity of the œsophagus and in Meckel's diverticulum. The one common feature of these situations is the presence of acid gastric juice.

Acute and chronic gastritis are frequently associated with localised loss of the superficial tissue, which varies in size from minute erosions only recognisable on microscopical examination to acute ulcers which are more or less easily recognisable with the naked eye. Acute ulcers occur in any part of the stomach, in the duodenal bulb, and in the region of the anastomosis after gastro-jejunostomy or partial gastrectomy. The vast majority of erosions and acute ulcers heal rapidly, but if one occurs in an individual with the hypersthenic gastric diathesis it is likely to become chronic. Probably all chronic ulcers have this origin. The various conditions already described which give rise to gastritis can thus also be regarded as factors in the development of chronic ulcers.

The tendency to develop a chronic duodenal ulcer is increased by excessive smoking ; the nicotine apparently acts through the autonomic nervous system by exaggerating the already excessive motor and secretory activity of the stomach.

One of the oldest theories of the origin of gastric ulcer was that the occlusion of small blood vessels led to local anæmia of the mucous membrane

which allowed digestion by the gastric juice to occur. It seems not unlikely that vasomotor spasm may be one factor, as something of this kind could alone explain the undoubted influence of emotional upsets and to a less extent of sudden change of temperature in the production of relapses of gastric and especially of duodenal ulcer.

Acute Gastric and Duodenal Ulcer

Symptoms.—An acute ulcer gives rise to no symptoms unless it causes hæmorrhage, which is often profuse but very rarely fatal, or, in very exceptional cases, perforation. Hæmorrhage or perforation occurring without any previous indigestion is thus usually due to an acute ulcer. The gastritis, of which it is a complication, is often completely latent, but it may give rise to any of the symptoms described on p. 584.

Acute duodenal ulcer is the most common cause of *melæna neonatorum*. Less frequently it causes hæmatemesis, and it may also give rise to vomiting and marasmus without obvious hæmorrhage during the first four months of life.

Prognosis.—Acute ulcers can develop into chronic ulcers, but the majority heal rapidly, leaving no trace of their presence. There is a great tendency to relapse, but the patient is able to take a full diet without discomfort between the attacks.

Treatment.—For the treatment of the hæmorrhage, see Hæmatemesis. All possible causes of gastric irritation should be dealt with, the after-treatment being that of chronic ulcer. The patient should be kept in bed on a strict ulcer diet until no occult blood has been present in three consecutive stools. The diet can then be rapidly increased.

Chronic Gastric Ulcer

Symptoms.—The onset is generally insidious, the symptoms first appearing after big or indigestible meals. The pain, which is often burning in character and may be very severe, is situated in the middle or slightly to the left of the epigastrium and may radiate upwards and to the back; it is much increased by indigestible food and generally disappears with a milk diet. In ulcers situated near the cardia it begins almost immediately after meals, and in prepyloric ulcers two or three hours after, intermediate intervals indicating an ulcer on the lesser curvature. The pain generally disappears spontaneously after about an hour. It is completely relieved by vomiting and by alkalis, but as a rule only partially by food. Some relief may follow lying down and the application of warmth to the epigastrium.

A small area of tenderness, the position of which is constant for each case, may be present in the epigastrium. It is more severe than in any other gastric disease; it is most marked in the presence of spontaneous pain. It is associated with rigidity of the left rectus.

With increasing pain vomiting appears; it occurs at the height of the pain, a small quantity of acid fluid with a little well-digested food being brought up. When the pain is severe, vomiting is often induced by the patient and may eventually develop into a voluntary act.

Occult blood is almost always found in the stools and vomited material, but disappears slowly when the patient is dieted. In about 25 per cent. of cases obvious hæmatemesis occurs: when the blood is abundant it is bright in colour and the stools are tarry; when less abundant it is coffee-coloured and mixed with food, and is recognisable in the stools only by chemical and spectroscopic examination. Melæna may also occur without hæmatemesis, but much less frequently than in duodenal ulcer.

The appetite is good at first and the tongue is clean, but fear of pain may lead to diminished intake of food with consequent loss of weight and weakness; in some cases, however, the relief given by food encourages the patient to eat heartily. Constipation is commonly present.

In uncomplicated cases there may be some delay in evacuation owing to reflex achalasia of the pyloric sphincter; in rare cases of lesser curvature ulcer I have seen 12 and even 24 hours' gastric stasis, probably the result of obstruction by the associated gastritis. A spasmodic narrowing is sometimes observed with the X-rays in the centre of the stomach when the ulcer is situated on the lesser curvature (*vide* p. 601). Conclusive evidence as to its position is almost always obtainable by the discovery of a "niche" formed by the crater of a chronic ulcer, which is filled with the opaque salt and is the site of the maximum tenderness.

A test-meal gives no constant result, but hyperchlorhydria is much more common than in normal individuals. In very chronic cases hypochlorhydria and even achlorhydria may be present, but these are caused by the associated chronic gastritis, as a second test-meal given after the ulcer has healed shows a considerable increase in acidity and often hyperchlorhydria, the treatment having led to disappearance of the gastritis.

Diagnosis.—A presumptive diagnosis of gastric ulcer may generally be made from the symptoms if hæmatemesis has occurred, but in its absence it is impossible to be certain without the aid of the X-rays. If the latter do not reveal the presence of a niche, a chronic ulcer can generally be excluded, but gastroscopy occasionally reveals a small chronic ulcer which has escaped recognition with the X-rays. The diagnosis is confirmed by the presence of occult blood in the stools. For the diagnosis from other conditions causing hæmatemesis, *vide* p. 580.

In cancer free hydrochloric acid is absent in 60 per cent. of cases; a chronic ulcer may give rise to a palpable tender tumour, but much less frequently than cancer, in which anorexia and wasting are also likely to be present. In chronic gastritis discomfort rather than pain is present; it generally begins directly after meals, and there is no localised tenderness. For the diagnosis of œsophageal and duodenal from gastric ulcer, *vide* pp. 554 and 591. The gastric symptoms associated with cholecystitis and recurrent subacute appendicitis may simulate ulcer, but the relation of the pain to the nature and time of meals is less regular, and less relief is given by alkalis; tenderness is present over the gall-bladder in addition to the epigastrium. It should be remembered that cholecystitis and appendicitis may be associated with gastric ulcer. With good technique it ought always to be possible to settle the diagnosis by means of the X-rays.

Complications.—Perforation of an anterior ulcer leads to general peritonitis (*vide* p. 753). It is rare for a gastric ulcer to be situated sufficiently near the pylorus to cause obstruction on healing, but the swelling and œdema

round a prepyloric ulcer together with reflex interference with the normal relaxation of the sphincter often result in temporary pyloric obstruction which disappears when the ulcer heals as a result of treatment. Recurrent cicatrisation over a period of many years of a large and very chronic ulcer in the body of the stomach in women may cause hour-glass constriction. Very chronic gastric ulcers, especially in the prepyloric region, occasionally become carcinomatous (p. 596), but such ulcers may form definite tumours without being malignant. The earlier onset, increased severity and absence of remission of pain should suggest the possibility of malignant degeneration.

Chronic Duodenal Ulcer

Symptoms.—The earliest symptom of duodenal ulcer is generally a sense of discomfort or fullness three hours after the largest meals. This is gradually replaced by pain, which occurs between two and four hours after every meal, the interval being longer the larger the meal. It frequently wakes the patient in the early part of the night, particularly if the last meal was finished less than three hours before going to sleep. It is generally situated in the middle line rather nearer the umbilicus than the ensiform cartilage; it may radiate to the right or be situated on the right side only; in rare cases it is on the left. The pain is often associated with a feeling of hunger and is relieved by taking food; it is therefore commonly known as "hunger pain." It is also relieved by alkalis and when the stomach is emptied by vomiting, which is, however, rare in uncomplicated cases, though regurgitation of mouthfuls of scalding, very acid, fluid may occur when the pain is at its height.

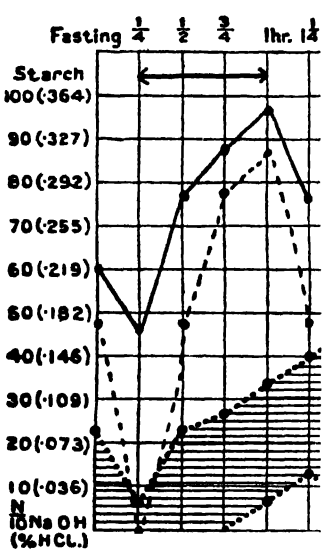

Fig. 16.—Fractional test-meal in case of duodenal ulcer, showing hyperchlorhydria and rapid evacuation. Continuous line, total acidity; dotted line, free HCl; shaded area, limits of free HCl in 80 per cent. of 100 healthy students.

Constipation is almost always present. The appetite remains good, and the patient does not lose weight or strength.

Periods of hunger pain lasting some weeks or months alternate with periods of more or less complete freedom from symptoms. The attacks are more common in cold weather than in hot, but the autumn and early spring are generally more trying than winter. Attacks are liable to be brought on suddenly by worry, exposure to cold, an acute naso-pharyngeal or bronchial infection, an indigestible meal, and excessive smoking or drinking.

In the large majority of cases occult blood is found in the stools. Severe hæmorrhage occurs in about 25 per cent. of cases: it always results in melæna and may also give rise to hæmatemesis.

In early cases the X-rays show that the stomach is often of the short high type and empties itself with unusual rapidity. In more chronic cases reflex achalasia of the pyloric sphincter may lead to delayed evacuation and consequent increase in size of the stomach, the greater curvature of which then reaches below the umbilicus. Irregularity in the outline of the duodenal bulb, due partly to the deformity caused by the ulcer itself and partly to secondary spasm, is always found, and affords conclusive evidence that an ulcer has been present, but unless it is tender or a definite niche is seen, the deformity may be produced by the scar of a healed ulcer. The niche formed by an ulcer on the lesser curvature of the duodenal bulb can be recognised in the silhouette of the bulb; one on the anterior or posterior wall can only be recognised when a radiograph is taken whilst the bulb is being compressed. A test-meal generally shows hyperchlorhydria with a climbing curve and hypersecretion (Fig. 16); if a lower curve is obtained, this is generally due to associated gastritis, and is replaced by a high curve if the meal is repeated when treatment has resulted in healing of the ulcer and disappearance of the gastritis.

Diagnosis.—When the symptoms have been present for a short time only, an actual ulcer is not as a rule present, but a pre-ulcerative duodenitis, which may be associated with a rapidly emptying duodenal bulb but no constant X-ray deformity and occult blood in the stools; it is likely to result in ulcer if not adequately treated. Excessive smoking, over-fatigue and anxiety may give rise to almost identical symptoms in individuals with the hypersthenic gastric diathesis, but the X-rays show no abnormality and occult blood is absent from the stools.

The diagnosis from gastric ulcer depends upon the later onset of pain, the greater relief on taking food, the rarity of vomiting, the greater frequency of a climbing hyperchlorhydric curve obtained with a fractional test-meal, the frequent situation of pain and tenderness to the right of the middle line, the more frequent periods of complete freedom from symptoms, and the results of X-ray examination, which occasionally, however, reveals the presence of an ulcer in the stomach as well as in the duodenum. Hæmatemesis without melæna is much more common in gastric than in duodenal ulcer, and melæna only is more common in duodenal ulcer. The symptoms may closely resemble those of cholecystitis, but in the latter condition the pain is much less regular in its time relations, the tenderness is over the gall-bladder, and evidence of gall-bladder disease is obtained by cholecystography and duodenal intubation. In rare cases cancer and syphilis of the stomach may produce similar symptoms, but the presence of achlorhydria and the X-ray examination should prevent a mistake in diagnosis.

Complications.—The inflammatory swelling round a large ulcer may lead to obstruction, the first symptom of which is generally vomiting. In very chronic cases cicatricial obstruction may develop.

Perforation may occur and lead to general peritonitis, or, much less commonly, to a localised abscess. Sub-diaphragmatic abscesses, due to duodenal ulcer, are always to the right of the suspensory ligament; unlike those secondary to appendicitis, they may contain gas. Duodenal ulcers differ from gastric ulcers in showing no tendency to become malignant, probably owing to the absence of the powerful peristaltic waves which rub hard particles of food against an ulcer in the stomach.

Treatment of Chronic Gastric and Duodenal Ulcer[1]

The patient should be kept warm in bed throughout the treatment, but he should get up every day to have a bath and to open his bowels, the difficulties with which are greatly reduced if a bed-pan can be avoided. No smoking should be permitted during the period of strict treatment.

The object of dietetic and drug treatment is to reduce the secretion of gastric juice as much as possible, and to keep the hydrochloric acid in the stomach completely neutralised. The evidence is conclusive that free hydrochloric acid delays the healing of an ulcer, whatever additional factors may have contributed towards its production in the first instance. At the same time as much food as possible is required to maintain the patient's nutrition, especially when he has lost much weight, as is often the case with gastric, though rarely with duodenal ulcer. Finally, the food should be as unirritating in its mechanical and chemical characteristics as possible.

Five ounces of milk, which can be flavoured with tea or cocoa, are given every other hour from 8 a.m. to 10 p.m., an equal quantity of custard, junket or other milky food, or white vegetable purée being given at the odd hours. To each milk feed 10 grains of sodium citrate are added. It is a valuable alkali, and by combining with the lime in the milk it prevents the formation of clots by the rennin of the gastric juice. An additional feed should be given each time the patient wakes during the night. Thin bread and butter, rusks and one or two coddled eggs can be safely added to the diet; they should be thoroughly chewed, and the fluid feeds should be slowly sipped. Apple or other fruit jelly may be used to flavour some of the feeds, and an ounce of strained orange juice should be given three times a day. Immediately before three of the feeds half an ounce of olive oil is taken, and an ounce of cream is added to three of the other feeds. The oil inhibits the secretion of gastric juice; at the same time it supplies a digestible and unirritating food of very high nutritive value in a concentrated form. Immediately before two other feeds $\frac{1}{150}$ gr. of atropine sulphate is given in 60 minims of water, and double the dose at night. The dose is increased by 10 minims every day till the maximum the patient can take without unpleasant dryness of the mouth or paralysis of accommodation. This varies in different individuals from gr. $\frac{1}{150}$ and $\frac{1}{75}$ at night to $\frac{1}{50}$ and $\frac{1}{25}$ respectively.

Thirty grains of magnesium trisilicate should be given half-way between meals and 60 grains last thing at night. It absorbs and neutralises acid so efficiently that on this regime very little free acid appears in the stomach except in the night. It does not, however, affect the reaction of the body fluids, and in contrast with all the usual alkalis it can, therefore, be given in unlimited doses without fear of causing alkalosis. Sodium bicarbonate and magnesia have the further disadvantage of stimulating the secretion of more acid after they have neutralised what is present in the stomach at the moment.

If the ulcer is in the neighbourhood of the pylorus and is giving rise to any obstruction, continuous hypersecretion of gastric juice will occur throughout the night. It is then impossible for the ulcer to heal, and in the past it has been supposed that such cases require operation. But the obstruction is generally due entirely or in great part to surrounding œdema and inflammatory swelling and pyloric achalasia or spasm, and in such cases, if the ulcer

[1] For the treatment of hæmorrhage *vide* p. 580.

can be caused to heal, any scarring produced is insufficient to give rise to obstruction. No feed should be taken after 6 p.m., and at 10 p.m., immediately before the last alkaline powder is given, the stomach is completely emptied by Senoran's evacuator; if not more than 4 ounces of fluid are present on two consecutive nights this can be discontinued. A double dose of the atropine is then given in order to inhibit the further secretion of gastric juice. In most cases the continued nocturnal secretion is rapidly controlled by this treatment.

Constipation can generally be prevented by the use of magnesia or liquid paraffin, but if the bowels are not opened on two consecutive days an enema should be given.

The strict treatment should be continued until, for at least 2 weeks, the patient has had no spontaneous pain and no trace of tenderness or rigidity, no occult blood has been found in the stools, and the X-rays no longer show the presence of an ulcer crater. A gastric ulcer should not be regarded as cured until gastroscopy shows that healing is complete; the crater may be filled with granulation tissue so that no niche is seen with the X-rays a fortnight or more before it is replaced by mucous membrane. In no case should the strict treatment last for less than 4 weeks, and for large and chronic ulcers 8 or 12 weeks may be required. The pain generally disappears within 48 hours; the other signs of activity disappear considerably later, the exact time depending upon the size and age of the ulcer and its proximity to the pylorus.

The diet can now be rapidly increased until at the end of a fortnight everything is taken with the exceptions I shall presently enumerate. It is not difficult to cause an ulcer to heal by suitable treatment in bed, but the predisposing causes are still present, and the exciting causes may still be operative unless special precautions are taken to prevent a recurrence. It is advisable to give instructions in writing for the patient to follow (*vide infra*).

From the beginning of treatment the swallowing of infective material should be kept in check as far as possible by careful dental hygiene, and as soon as the patient is convalescent thorough treatment of the teeth should be undertaken, and the patient should subsequently have his teeth put into good order at least twice a year. Any infective foci in the throat and nose should also be treated.

The patient should eat slowly and masticate thoroughly. It is a good plan to give him solid food during the last days he remains under strict observation, so that he may get into the habit of eating slowly, for when the habit is once acquired it is easy to continue in the same way. It should be impressed upon busy men that when they have no time to sit down to a proper meal it is better to drink some milk or eat some plain chocolate than to bolt some less digestible solid food. Tough meat, new bread and other articles of diet which cannot easily be chewed to a fluid consistence should be prohibited. The patient should avoid the pips and skins of fruit, whether raw, cooked or in jam, cake or puddings, and pickles, salads and all uncooked vegetables, such as celery; green vegetables are best given as purées with butter, but spinach, which is a very powerful stimulant of gastric secretion, should be permanently avoided. No strong tea or coffee, no aerated drinks, and no alcohol should be allowed, except a little diluted whisky or light wine with meals for those who feel the need of it. Condiments, vinegar, and unripe and acid fruit, high game,

sausages and curry should be prohibited. The patient should be allowed to smoke only in strict moderation. He should remain on this regime until he has been free from symptoms for two years, and should follow it in a modified form for the rest of his life.
